Food and Feeding. Omnivorous predator and scavenger; strongly insectivorous. Feeds mainly on invertebrates, small birds, eggs, nestlings, small mammals and carrion; occasionally reptiles. Also seeds, some fruit, other plant material, occasionally nectar. Occasionally attacks moribund lambs. Opportunistic, feeding mainly on the ground in open habitats; also in trees. Forages mainly by walking and gleaning from the ground or low vegetation, or by snatching prey from foliage. Commonly patrols roads, sheep paddocks, rubbish dumps and parks for carrion and refuse. Sometimes dunks food scraps in water before eating. Caches surplus food in hiding places, such as under bark of tree; caching observed also in captivity. Forages mostly in small to large flocks.
Breeding. Laying mainly late winter to spring, mostly early Jul to mid-Nov (peak mid-Aug to early Oct), but can start as early as mid-May and (in alps) extend to early Dec; failed pairs renest, often successfully. Monogamous. Semi-colonial nester in clumped pairs in small territories (1–4 ha) used only for breeding, or as more dispersed pairs where tree cover sparse. Nest a large bowl of sticks, lined with bark, grass, feathers, wool, hair and/or human rubbish, built 1–55 m (commonly less than 10 m) above ground in fork of tree or shrub or on artificial structure such as utility pole, tower or windmill platform, rarely on ground or cliff. Clutch 1–6 eggs, usually 3–5; incubation by female, period 19–20 days; chicks fed by both sexes, nestling period 34–39 days (mean 37 days); young remain in nest area for a week, after which family departs from nest area with mobile flock; juveniles still fed by parents 1 month after leaving nest, but disperse up to 450 km within 2–3 months of fledging. Adults seen to feed fledgling Channel-billed Cuckoo (*Scythrops novaehollandiae*). Breeding success measured as 75% hatching success and 36% fledging success for 2250 eggs in 534 clutches, 32% of clutches failed, giving mean of 1·5 fledglings per nest; in another sample, of 298 nests, 49% produced fledglings. Age at first breeding 3 years.
Movements. Breeding pairs resident only for duration of breeding cycle, and commute daily to foraging areas up to 15 km away; form post-breeding flocks of up to 30 individuals, which roam within 20 km of nesting territories. Juveniles, immatures and non-breeding adults form mobile flocks of typically 30 or more individuals, sometimes 200–300 birds, which disperse or migrate up to 450 km; some eventually return to natal site to breed.
Status and Conservation. Not globally threatened. Abundant and widespread; has increased in range and numbers with spread of agriculture and urbanization. Benefits from artificial food sources, and is common in modified habitats. Has perceived pest status in sheep-rearing lands, orchards, crops, around poultry and in cities, and consequently is legally unprotected and is persecuted by shooting, trapping and poisoning in farmland (with little apparent effect on numbers). Well represented in protected areas.

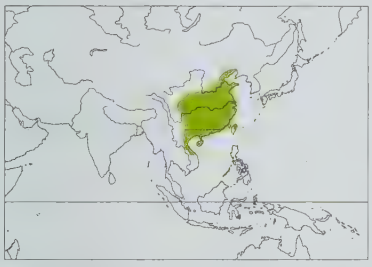
113. Forest Raven

Corvus tasmanicus

French: Corbeau de Tasmanie **German**: Tasmankrähe **Spanish**: Cuervo de Tasmania
Other common names: New England/Relict Raven

Taxonomy. *Corvus marianae tasmanicus* Mathews, 1912, Tasmania.
Formerly considered a race of *C. coronoides*. Has been suggested that race *boreus* (sometimes referred to erroneously as *novaanglica*) merits treatment as a full species, though without supporting evidence; recent studies of vocalizations indicate that current treatment is appropriate. Two subspecies recognized.
Subspecies and Distribution.
C. t. boreus I. Rowley, 1970 – NE New South Wales, in E Australia.
C. t. tasmanicus Mathews, 1912 – coast of extreme SE Australia, islands in Bass Strait and Tasmania.

Descriptive notes. 52–54 cm; male 500–800 g and female 535–755 g (nominate), male 550–740 g and female 600–710 g (*boreus*). Large, long-legged crow with stout bill, medium-length bifurcated throat hackles, blunt wings and short tail. Plumage is entirely glossy black, with grey feather bases on head and neck; iris white; bill and legs black. Sexes similar. Juvenile is duller than adult, with shorter hackles, pink gape and gular skin, blue-grey (fledgling) to brown eyes; older immature (in 2nd–3rd year) has eyes brown, becoming hazel. Race *boreus* is like nominate in plumage, but has longer wings and tail, proportions thus more as those of *C. coronoides* (but in flight has rounded, broad-based wings and broad tail). Voice. Series of deep (bass), slow and guttural caws, given with throat hackles noticeably fanned and tail deeply depressed, typically of 4 notes, with terminal note drawn out and descending. Also gives shorter, sharper barks, sometimes antiphonally, and guttural croaking notes. Calls deeper and harsher than those of *C. coronoides*; richer and often more leisurely than calls of *C. mellori*.
Habitat. All terrestrial habitat types within range, from subalpine (1500 m) to littoral, including dense forest, though rarely within or below rainforest canopy. Most common in woodland and pastoral land; often on edge between wooded and open areas. Habitats typically dominated by eucalypts (*Eucalyptus*), but occurs also in other vegetation types, including exotic pine (*Pinus*) plantations.
Food and Feeding. Omnivorous predator and scavenger; strongly carnivorous. Feeds mainly on invertebrates, small birds, eggs, nestlings, small mammals and carrion, including beachcast marine life; occasionally lizards. Also seeds, some fruit, other plant material, occasionally nectar. Sometimes attacks weak or moribund lambs. Opportunistic, feeding mainly on the ground in open habitats, sometimes in trees and shrubs. Forages mainly by walking and gleaning from the ground or low vegetation, sometimes gleaning or snatching prey in foliage; occasionally wades in shallow water. Commonly patrols roads, sheep paddocks, rubbish dumps and parks for carrion and refuse. Sometimes dunks food in water before eating. Caches or buries surplus food in terrestrial sites, such as under soil or grass or in grass tussocks, and especially in arboreal hiding places, such as



crevices in trees, behind loose bark, or under leaves placed in purpose-built stick platform; retrieves stored food later. Forages in pairs and family parties; also in larger flocks of non-breeders.
Breeding. Laying mainly late winter to spring, mostly Jul–Sept, but extending to early summer (mid-Dec) in Tasmania. Monogamous. Solitary nester, in well-dispersed pairs. Nest a large bowl c. 40 cm wide and 50 cm deep, made with sticks, lined with bark, leaves, feathers, grass, wool, fur, seaweed and/or horse manure, built 3–36 m (usually more than 10 m) above ground in fork of tree; on offshore islands sometimes on or near ground or on rock ledge. Clutch 3–6 eggs, usually 4 or 5; incubation by female, period probably c. 20 days; chicks fed by both sexes, nestling period 37–43 days; young remain dependent for a further three months. Nests occasionally parasitized by Channel-billed Cuckoo (*Scythrops novaehollandiae*). Broods of three fledglings common; one pair raised 11 young over six years, giving average of 1·8 young per attempt. Age at first breeding 3 years.
Movements. Breeding pairs sedentary within large home range. Juveniles, immatures and non-breeding adults form mobile, dispersive flocks of typically 10–30 individuals, sometimes congregating in flocks of up to 100 or more at gluts of food. Commonly makes sea crossings of 10–30 km between islands. Many individuals apparently remain within 100 km of natal site, although groups readily cross Bass Strait between Tasmania and mainland Australia, involving sea crossings of up to 90 km.
Status and Conservation. Not globally threatened. Abundant and widespread in Tasmania. Populations in coastal SE mainland Australia small and fragmented. N race *boreus* considered "Near-threatened" nationally on account of small, fragmented and declining populations, which are subject to habitat loss and to competition from expanding populations of *C. coronoides* and *C. orru*. In Tasmania, has probably increased in numbers with spread of agriculture and urbanization; lives in home range of c. 100 ha in pastoral areas, to 300–400 ha in coastal forest. Benefits from artificial food sources, and is common in modified habitats. Has perceived pest status in sheep-rearing lands, orchards, crops and around poultry, and consequently is legally unprotected and is persecuted by shooting, trapping and poisoning in farmland (with little apparent effect on numbers). Well represented in protected areas.
Bibliography. Debus (1982, 1984, 1996), Debus & Rose (2006), Fell (1987), Fitzsimons (2003), Higgins *et al.* (2006a), Kloot (1980), Lawrence (2005), Madge & Burn (1994), McCulloch & Thompson (1987), Morcombe (2000), Pizzey & Knight (1998), Rowley (1969a, 1970, 1973a, 1973b, 1973c, 1974), Rowley & Vestjens (1973), Rowley *et al.* (1973), Schodde & Mason (1999), Schodde & Tidemann (1986), Secomb (1997, 2005a, 2005b), Simpson & Day (1996), Slater *et al.* (2003).

114. **Collared Crow**

Corvus pectoralis

French: Corbeau à collier **German**: Halsbandkrähe **Spanish**: Cuervo Acollarado
Other common names: White-necked Crow(!)

Taxonomy. *Corvus pectoralis* Gould, 1836, China.
Formerly known as *C. torquatus*, but that name invalid, as preoccupied. Possibly part of the superspecies formed by *C. corone* and *C. cornix*. Monotypic.
Distribution. Lowland C, E & SE China from S Gansu and Shaanxi E to Liaoning, Hebei and Shandong, S to Sichuan, Yunnan, Hainan I, Guangdong and Fujian, Taiwan (including small island of Kinmen, off Fujian), and Vietnam (lowland E Tonkin S to C Annam).

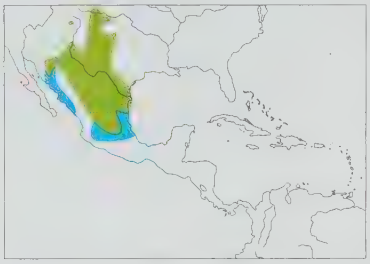
Descriptive notes. 50–55 cm; 347–512 g. A distinctive pied crow with pointed throat feathers; structurally similar to *C. corone*, but slightly larger size, relatively longer wing and tail, more prominently fingered primaries, and usually slightly slimmer bill (impression created by somewhat straighter culmen). Most of plumage is black, glossed purplish, bluish and greenish, with starkly contrasting wide white collar which extends over nape, upper mantle and side of neck and across lower breast (white feathers have grey bases); iris dark brown; bill and legs black. Sexes similar. Juvenile has looser, softer plumage with white areas washed grey, probably also has paler and greyer iris and pinkish-red interior of mandibles, but clarification needed. Voice. Typical call a rolling, hoarse "kaaarr", also repeated less forcefully as "kaar-kaar". Reported as uttering variety of cawing, clicking and creaking sounds, but calls generally higher in pitch than those of congeners, especially *C. macrorhynchos*.
Habitat. Inhabits very low-lying agricultural land, occasionally on higher ground. Riverine plains with scattered trees and extensive rice paddies favoured; found also in lightly wooded country near water or marshes, but avoids more heavily wooded or hilly country inhabited by *C. macrorhynchos*. Less frequently in parks or gardens, or in towns.
Food and Feeding. Omnivorous, but far less of a scavenger than either *C. corone* or *C. macrorhynchos*. Diet in need of study; consists chiefly of invertebrates (mainly insects and their larvae), small crustaceans and molluscs, with a certain amount of grain, including rice; some edible refuse taken, but little in the way of carrion. Feeds almost entirely on ground, foraging along canal banks and in shallow water at edges of marshes, pools, rice paddies and riversides. In captivity, dunks messy food items in water, afterwards holding the item under the foot and breaking it into pieces; presumed to do so also in the wild. Rather solitary by nature, generally met with in pairs or family parties; may sometimes associate with *C. dauuricus* and *C. macrorhynchos*.
Breeding. Season commences in early Feb in S China, young fledging at end Mar. Presumed to have monogamous long-term pair-bond. Solitary nester. Rather large nest based on sticks and twigs, with lining of soft plant materials and animal fur, constructed within crown of large tree. Clutch 2–6 eggs, average 4; no information on incubation and nestling periods.
Movements. Resident in S portions of range; many in N (and probably W) withdraw S to milder coastal areas of S China in winter. Unusual during any season further N than Beijing, but vagrants have been reported N to SW Heilongjiang and on Taiwan.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Surprisingly poorly studied for so widespread a species. Uncommon; decreasing. Was thought to be relatively numerous over much of SE China, but has recently suffered a decrease in its population and a contraction in its range. Now present regularly at rather few sites; two localities in Hong Kong (Plover Cove and Deep Bay areas) appear to be important strongholds. Now very rare in Taiwan, where possibly no longer breeds; numbers on Kinmen I drastically reduced, from flocks of hundreds in 1990s to single-figure groups. Status in Vietnam requires investigation; only three recent records, and possibly no longer breeds there. Reduction in numbers, at least in China, believed due to loss of food supplies owing to agricultural intensification and consequent over-use of pesticides; in some areas this exacerbated by human persecution. As the decline appears to be continuing, the conservation status of this species requires careful monitoring.
Bibliography. Anon. (2008p), Chen Fuguan *et al.* (1998), Cheng Tsohsin (1976), Goodwin (1986), Lei Jinyu & Liu Yang (2006), Liu Yang & Lei Jinyu (2005), MacKinnon & Phillipps (2000), Madge & Burn (1994), Meyer de Schauensee (1984), Nguyên Cu *et al.* (2000), Robson (2000), Vaurie (1959), Wildash (1968).

115. **Hawaiian Crow**

Corvus hawaiiensis

French: Corneille d'Hawaï **German**: Hawaiikrähe **Spanish**: Cuervo Hawaiano
Other common names: 'Alala

Taxonomy. *Corvus hawaiiensis* Peale, 1848, a few miles inland from village of Kaawaloa, Hawaii.
In earlier literature often referred to erroneously as *C. tropicus*. Preliminary genetic analysis suggests that this species may be more closely related to *C. corax* than to other crows, a conclusion supported by morphological features (including large size, especially of bill) and vocalizations. Monotypic.
Distribution. Formerly occurred on Hawaii (and probably Maui), in Hawaiian Is.



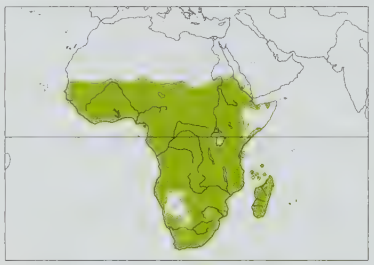
Descriptive notes. 48–52 cm; male average 555 g, female 485 g (released captive-reared birds). A medium-sized crow with a relatively large head, long legs, squarish tail and stout, moderately arched bill; conspicuous nasal tuft covering base of culmen; fine bristle-like throat feathers. Plumage is dull, unglossed black, body feathers with dull grey bases, wing dull dark brown (primaries with brown outer webs); iris dark brown; bill and legs black. Sexes similar, males 3–9% larger than female in all measurements. Juvenile has plumage rather fluffy, dull dark plumbeous-grey; iris blue, lining of mouth pink. Voice. Loud, rich repertoire of graded calls poorly understood. Male apparently more vocal than female, especially in giving loud "aa-wooop" calls for long-distance territory defence; neighbouring males duel vocally, often matching each other's loud screams, whoops, howls, and yells for over 20 minutes. Loud "caw", "whaaa", "all-woo" and "aa-waaooop" used also for advertising location of territory and group-members. Aggression often punctuated with shrieks, quick barks, and growls; when threatened, high pitched "caw" or shriek often ends with growl. High-pitched "raa-raa" series as contact call among family-members. Nest defended with loud, raucous series of "caw-caw-caw". Begging call of female and dependent young "whaaa-whaaa-whaaa". Male gives low-pitched "owww-owww-owww" growl ending in "aaow-woop" or shriek prior to copulation, while female gives begging call. Soft "arraagh-aaraagh" or "rraack-rraack" between mates. Increasingly intense, ascending series of "caw-caw" when mobbing predators and intruding crows. Descending "raak-raaak-raaaak" when pursued.
Habitat. Inhabited heterogeneous wet and dry forests frequently affected by volcanic eruption. Forests characterized by 'ohi'a (*Metosideros polymorpha*), mamane (*Sophora chysophylla*), naio (*Myoporum sandwicense*) and koa (*Acacia koa*) trees; tree-ferns and a diversity of tropical shrubs and vines fill in the thick lush forests and provide important foods.
Food and Feeding. Omnivorous. Wide variety of fruits, nuts and invertebrates; eggs and nestlings of other birds; flower nectar. Isopods, spiders (Araneae) and many other invertebrates comprise bulk of diet, followed by fruits and other plant parts. Pilo (*Coprosma rhynchocarpa*), 'ie'ie (*Freycinetia arborea*) and ho'awa (*Pittosporum*), 'olapa (*Cheirodendron trigynum*), 'oha kepau (*Clermontia*), mamaki (*Pipterus albidus*), 'akala (*Rubus hawaiiensis*), manono (*Hedyotis*), pukiawe (*Styphelia tameiameiae*), 'aiea (*Nothocestrum*) and 'ohelo (*Vaccinium calycinum*) provide important native berries and nuts; introduced guava (*Psidium cattleianum* and *Psidium guajava*) and Christmas berry (*Schinus terebinthifolius*) may provide food at lower elevations. Nestling diet becomes especially rich in protein, e.g. birds, eggs, mice (Muridae) and invertebrates, as young develop; food brought to nestlings appears out of proportion to availability (adults eat native foods primarily in proportion to availability). Forages in trees, shrubs, and native vines such as *Freycinetia arborea*, and occasionally on the ground. Probes flowers for nectar; uses tree crotches as anvils on which it hammers hard nuts to open them, but not known to drop nuts to facilitate opening.
Breeding. Nest-building early Mar to early Jun. Large stick nest (stick diameter 2–12 mm), lined with moss, grass, rootlets and other fine material, external diameter 45 cm, height 24 cm, internal diameter 19–20 cm, depth 7 cm, built in tree; territory-owners exclude other breeders from area within 1–4 km of nest-site. Clutch 1–5 eggs, usually 3; incubation by female, period 20 days; chicks brooded by female, fed by both parents, nestling period 6 weeks; young fly poorly for several days to 2 weeks after fledging, increasing vulnerability to introduced mammalian predators. Annual productivity low, 1·1–1·4 fledglings per successful nest. Adult survival high; a wild female lived for 18 years and a captive male for 25 years.
Movements. Resident. In the past, moved to higher elevation after nesting when *Freycinetia arborea* fruit became scarce at low levels; dispersal of up to 6·8 km observed.
Status and Conservation. EXTINCT IN THE WILD. Restricted-range species: present in Hawai'i EBA. Formerly occurred on Hawaii (and probably on Maui). Last wild population occupied less than 20 km² of forest on W slope of Mauna Loa (1000–1890 m), on Hawaii; last wild individual seen in summer of 2002. Captive population exists, in 2006 consisting of 38 individuals at the Keauhou Bird Conservation Centre (Hawaii) and 15 at the Maui Bird Conservation Centre; 28 of these are used in a captive-breeding programme. The extinction of this species in the wild resulted from a combination of factors. Activities of early human settlers (Polynesian) several hundred years ago may have eliminated crow species on Maui (*C. viriosus*, *C. impluviatus*, and perhaps present species). More recently, eliminated from the island of Hawaii, the causes including: introduction of mosquitoes (Culicidae), disease (including malaria, pox virus, and toxoplasmosis), predators and competitors including rats (*Rattus*), mongoose (*Herpestes*), feral cats and alien birds; degradation of habitat leading to loss of native foodplants and increased grass and open forest, which favours the native Hawaiian Hawk (*Buteo solitarius*), a predator of present species; and shooting and trapping by people. Efforts in late 1990s (27 juveniles reared and released during 1993–1999) to augment the declining wild population were halted after predation on released crows by wild hawks increased; 21 of the released birds died from predation or disease. Techniques to breed, rear and release this species are established and validated, but future releases are pending further growth of the captive population and the management of limiting factors in the wild. Listing of this species as "endangered" in the USA has provided for recovery planning and significant financial investment in captive propagation, habitat acquisition, and management.
Bibliography. Anon. (2003d, 2008p), Banko *et al.* (2002), Butchart & Stattersfield (2004), Duckworth, Cade *et al.* (1992), Fleischer & McIntosh (2001), Fleischer *et al.* (1998), Griffin *et al.* (1987), Kuehler *et al.* (1995), Marzluff & Angell (2005), Meinertzhagen (1926), Pratt *et al.* (1987), Sakai *et al.* (1986), Stattersfield & Capper (2000).

116. Chihuahuan Raven

Corvus cryptoleucus

French: Corbeau à cou blanc **German**: Weißhalsrabe **Spanish**: Cuervo Llanero
Other common names: White-necked Raven(!), American White-necked Raven

Taxonomy. *Corvus cryptoleucus* Couch, 1854, Charco Escondido, Tamaulipas, Mexico.
Multiple analyses of mitochrondrial DNA suggest that present species is sister to the "California clade" of *C. corax*, these taxa differing by only 1·75% (all mitochondrial DNA) to 1·8% (cytochrome *b* only), indicating that they diverged between 1·1 and 0·6 million years ago (well after the two clades of *C. corax* diverged); this suggests that ancestor of present species may have been *C. corax* of "California clade" that became isolated in SW North America c. 1 million years ago. Monotypic.
Distribution. Breeds in SW USA in SE Colorado and from SE Arizona, S & E New Mexico, S Nebraska and S Kansas S to W Oklahoma and W & S Texas and in N Mexico S to NW & NC Sonora, NE Jalisco, Guanajuato, NW Hidalgo, Neuvo León and C Tamaulipas. Winters throughout breeding range and also in NW & C Mexico (NW coast, and Guadalajara and Michoacán).



Descriptive notes. 46–53 cm; 380–670 g. A moderately sized raven intermediate in many respects between *C. corax* and *C. brachyrhynchos*, with long wings, graduated pointed tail (appearing somewhat wedge-shaped in flight), large stout bill with extensive nasal bristles covering more than half of exposed culmen, long and lanceolate throat feathers. Plumage is black, with violet to purplish sheen dorsally, gloss appearing more bluish on underparts; downy basal parts of neck and breast feathers white (exposed by strong wind or during social display); iris dark brown; bill and legs black. Differs from *C. corax* in smaller size, white (not grey) bases of neck feathers, more extensive nasal bristles, and, in flight, more rounded (less wedge-shaped) tail. Sexes similar, male slightly larger than female. Juvenile is duller than adult, with slight metallic blue-green sheen, grey to dull white bases of neck and breast feathers, no lanceolate throat plumes; first-year like adult, but retained wing and tail generally dull (and often fade to brown), second-year like adult; base of bill gradually turns from yellowish to black during first year and mouth from red to black during first two years. Voice. Not well studied. Primary call a loud, harsh "kr-a-a-a-a", higher-pitched than "quork" of *C. corax* and lower-pitched and more guttural that "caw" of *C. brachyrhynchos*, given singly or in series with varying intensity (perhaps to indicate caller motivation); used both for contact and for scolding (no distinction noted). Other soft and varied calls include "ug-ug" during sexual displays, high-pitched food-begging calls of juveniles and perhaps females, faint "chirr" accompanying submissive display, and weird sounds during roost formation.
Habitat. In N of range, found in short-grass prairie where power poles, windmills and buildings provide nest-sites. In C & S portions of range, typically in desert grassland where shrubs and small trees, e.g. mesquite (*Prosopis*), acacia (*Acacia*) and yucca (*Yucca*), form islands among a sea of perennial grasses, mesquite–shinnery oak (*Prosopis–Quercus harvardii*) or creosote bush (*Larrea tridentata*) shrublands, dry desert grasslands, rolling hills at lower reaches of pinyon–juniper (*Pinus–Juniperus*) woodland, and edges of low-elevation riparian woodlands. Sea-level to 2400 m. In non-breeding season, congregates in agricultural fields and refuse dumps near towns.
Food and Feeding. Omnivore. Diet consists primarily of large insects, especially grasshoppers (Orthoptera), beetles (Coleoptera), Lepidoptera and bugs (Hemiptera), and small mammals, especially carrion of rabbits (*Sylvilagus* and *Lepus*); also eats variety of soft-kerneled grains (mostly sorghum and maize, during autumn and winter), native fruits, e.g. *Opuntia*, *Condalia* and *Celtis*, and cultivated nuts, e.g. pecan (*Carya illinoensis*); occasionally preys on bird eggs, nestlings and fledglings, including those of large species such as Wild Turkey (*Meleagris gallopavo*), and on reptiles, amphibians and fish. Nestling diet protein-rich, of insects and small animals. Often forages in flocks; non-breeders, and perhaps some foraging breeders, may form flocks of 50–200 individuals and forage over many square kilometres. Flock-members walk, hop and fly in loose, wave-like fronts. Chases insects and small animals, probes ground, turns over cow dung, follows ploughs, and patrols roadways in search of live prey and carrion; takes cues from other birds and people to find agricultural and other anthropogenic food bonanzas. Caches surplus food; social lifestyle, association with humans, and reliance on ephemeral and varied foods have likely favoured development of spatial and non-spatial memory, use of insight, and cultural inheritance; not studied in detail, but observations and laboratory tests indicate that this corvid remembers its cache locations and can rapidly learn to discriminate among numerical and non-numerical cues. Use of communal roosts increases throughout late summer and early autumn, commutes from roosts to concentrations of food, travelling up to 40 km or more from roosts at this time; in late autumn (Nov) and throughout winter, continues to forage widely in large flocks.
Breeding. Nest-building Apr in N of range, earlier in Mexico, laying mid-Apr (typically May) to late Jun. Nests slightly aggregated, often in clumps of 3–5 with inter-nest distance 200–1400 m, but can be more than 8 km apart; spacing may reflect variation in occurrence of suitable nesting sites or social constraints. Pair appears to defend area within 100 m of nests from conspecifics and forages to at least 10 km from nest. Bulky nest 31–61 cm in diameter and 36 cm deep, consisting of loose outer platform of interwoven thorny twigs (often mesquite) and soft inner cup (15–21 cm diameter, 13–15 cm deep) of mammal hair, shredded tree bark, yucca fibres, dry grass, feathers and moss, variety of artificial substances incorporated into cup (including wool, cotton, paper, burlap, twine and rope, rags, hog bristles) and outer platform (may be nearly entirely of wire); placed 1·5–20 m (usually 2–4 m) above ground in tree (often mesquite, but many others used), or on artificial structure such as pole, windmill, building, tower, oilfield machinery; typically in taller tree and surrounded by taller shrubs than expected from random placement. Clutch 1–8 eggs, usually 4–6; incubation by female, male assisting to some degree, period 18–22 days; hatching asynchronous, chicks brooded for several days, shaded as needed, nestling period 37–40 days; post-fledging care poorly known, 5–20 days or longer. Breeding success varies annually, greatest after wet springs when grasshoppers abundant. Oldest recorded individual was 12·5 years.
Movements. Relatively sedentary during breeding season. Dispersal poorly known, but early ringing studies in Texas (S USA) recovered 13 individuals within 40 km of natal area and one 72 km distant; some, if not most, adults appear to reoccupy breeding territory and likely maintain home range from year to year unless resources fail.
Status and Conservation. Not globally threatened. Status little known in Mexico; in USA, fairly common, and populations appear to be stable or slightly declining; exact breeding range imprecisely known because of confusion with *C. corax*. During 1966–1999, surveys in USA detected a non-significant annual decline of 1·72%. Range has gradually contracted, except in WC plains of USA, since extirpation of bison (*Bison bison*). Changing agricultural practices on plains of Colorado and Kansas may be affecting this decline in extreme NE of the range; locally, abundance and reproductive success vary annually, perhaps reflecting abundance of food, including insects and human subsidies. As it is a predator in a desert ecosystem, this corvid may be an important indicator of ecosystem function and a sentinel of change. May be vulnerable to variety of threats in the future. Human persecution has occurred in the past, and may reduce local populations perceived as agricultural pests or nuisances; this could become increasingly common if this species continues to expand into growing towns and cities. Droughts and new diseases are increasingly important. Loss of shinnery oak due to climatic, biotic or anthropogenic change may reduce orthopteran prey needed by ravens. Poisoning of rodents, reduction in jackrabbit numbers (directly or indirectly through habitat conversion) and use of insecticides will indirectly, and perhaps directly, reduce corvid abundance and productivity. West Nile Virus is an emerging disease along Rio Grande, and will likely reduce this species' populations in infected areas for at least several years. Because of its limited range and increasing threats facing it, this corvid could well become threatened in the future.
Bibliography. 117. Pied Crow

Corvus albus

French: Corbeau pie **German**: Schildrabe **Spanish**: Cuervo Pío
Other common names: African Pied Crow, White-bellied Crow

Taxonomy. *Corvus albus* Statius Müller, 1776, Senegal.
Forms a superspecies with *C. edithae* and *C. ruficollis*. Hybridizes frequently with former in NE of range; recent observations suggest that interbreeding is not immediate when the two meet, and that some time is required for breeding-cycle synchrony to develop. Despite extensive range of present species, little variation of any significance is apparent (birds in far N have somewhat larger bill than those in S), and no races have been described. Monotypic.
Distribution. Almost the whole of sub-Saharan Africa S from c. 17° N in Mauritania and Mali, C Chad and 20° N on Red Sea coast of Sudan (absent from extensive tracts of Eritrea, Ethiopia and Somalia, from the most arid regions of Namibia, W Botswana and Kalahari basin of NW South Africa, and from higher elevations of Lesotho); present on islands of Bioko (Fernando Póo), Zanzibar, Pemba and Mafia (off Tanzania), and Comoro Is, Aldabra, Glorieuses Is and Madagascar.

Descriptive notes. 45 cm; 400–700 g. Large corvid with tail of moderate length and distinctly graduated towards tip, throat feathers slightly elongated and mostly pointed. Has head, neck and upper chest black, glossed blue and purple, contrasting with white collar on upper mantle which broadens on underparts to extend over breast and foreflanks, and just onto axillaries; rest of upperparts (lower mantle to uppertail-coverts) and underparts (rear flanks, tibia and ventral area) dull, less glossy, black; upperwing and tail black, glossed with blue and purple; iris dark brown; bill and legs black. Sexes similar. Juvenile has black of head, wings and tail less glossed than adult, and feathers of head and undertail-coverts shorter and "looser", also demarcation between white and black areas of body less clear-cut owing to grey feather tips. Hybrids with *C. edithae* exhibit variety of grey shadings, or speckled breast and collar areas on body. Voice. Typical call a deep, guttural "kraaak", similar to those of both *C. frugilegus* and *C. corax*, varying in pitch, sometimes a deeper "rrawrr" or shorter, upslurred "krow" or rather flat "raa", the last often prolonged into almost cat-like "raaaaeow". Also gives dry double rattle, the first part of which often lower in pitch, "torrrrrrh-tarrrrrrh". Other calls include muffled nasal "klaang", hollow "klok-klok", throaty "glupp" and flat "ack-ack". Many of these calls very similar to those of *C. edithae* and may be accompanied by head-bobbing and tail movements.
Habitat. Open country, including grasslands, open woodlands, forest clearings, savanna, riverbanks and lakeshores. Freely about human habitation, foraging around farmsteads, villages and even towns and cities. Habitually visits rubbish dumps and slaughterhouses. Avoids dense forest, deserts and highly mountainous regions. From sea-level upwards, to 3700 m in Ethiopia, but most abundant at lower elevations.
Food and Feeding. Omnivorous. Takes all manner of invertebrates, including spiders (Araneae), ticks (Ixodoidea), beetles (Coleoptera), termites (Isoptera), grasshoppers and locusts (Orthoptera), and molluscs. Many small vertebrates also eaten, e.g. frogs, lizards, rodents, fish and small birds. Even capable of catching locusts, small birds and bats in flight, and reported as killing or injuring sickly newborn lambs. Familiar sight by roadside, where it patrols for kills; scavenges at rubbish bins and rubbish dumps, often with Black Kites (*Milvus migrans*) and Marabous (*Leptoptilos crumeniferus*). Recorded as favouring vegetable items in S of range, where it takes various seeds, roots and fruits; digs up sown grain, and breaks down maize plants by perching on them, then stripping kernels from cob when on ground. Other crop plants taken include oil palm nuts (*Elaeis guineensis*), cassava, dates, potatoes, rice and sorghum. Also eats fleshy part of coconuts and groundnuts. Raids birds nests, entering heronries to take nestlings and eggs; recorded as taking whole nest of a small bird in bill and flying away to enjoy its contents on a more convenient perch. Follows bush fires to take escaping insects; accompanies cattle and game animals, taking ectoparasites from their backs or from ground, and also follows the plough. Also reported as dropping stones from a height to break shells of Ostrich (*Struthio camelus*) eggs. Said to hide food items in sand under coconut palms. Forages in pairs and small groups; often in larger flocks at abundant food; roosts communally in stands of large trees, often in parks in cities and towns, where roosts can attract many hundreds or even a few thousand individuals.
Breeding. Season varies with onset of local rains: eggs reported Aug–Oct in Mauritania and Mali, Feb–Apr in Gambia, Apr–May in Chad, May–Jul in Burkina Faso, Jul–Aug in Niger, Mar–Jul in Nigeria, Apr–May in Ghana, Apr–Jun in Togo, Feb–Mar and Dec in Cameroon, Jan–Jul, Sept and Dec in Sudan, Feb–Apr in Ethiopia and Eritrea, Jan in Kenya, Jan–Feb and May–Oct in Uganda, throughout year in various parts of Tanzania, Jul–Feb in DRCongo, Oct in Gabon and PRCongo, May and Aug–Oct in Zambia, Jun and Sept–Nov in Malawi, Aug–Dec in Zimbabwe, Sept–Nov in

Botswana, Sept–Dec in Namibia, Sept in Lesotho, Jul–Jan (mostly Sept–Oct) in various parts of South Africa, and Aug–Dec (mostly Oct) in Madagascar. Monogamous, with probably lifelong pair-bond. Solitary nester. Nest built by both sexes, taking 11–12 days, a bulky structure of sticks, roots and sometimes wire, with deep cup lined with mud, dung, wool, string and grasses, usually in high tree fork, on telephone pole, pylon, artesian windmill or even tall building, rarely on cliff ledge; often same site used but freshly built nest constructed each year. Clutch 1–7 eggs, mostly 4 or 5; incubation by both sexes, female doing 75–80% of work and all of sitting overnight, period 18–19 days; chicks fed by both sexes, male alone feeds first-hatched chick for first few days while female incubates remaining eggs, nestling period 35–45 days. Nest occasionally parasitized by Great Spotted Cuckoo (*Clamator glandarius*).

Movements. Mainly sedentary. In wet years, N populations spread N into Saharan oases, some reaching 18° N (as at Nouakchott, in Mauritania) and can be common in C Chad, some reaching N Chad. In NW Central African Republic and W Sudan, seems to be present in good numbers only during Oct–May dry season, most moving out completely to breed. In Gambia, post-breeding movement from interior to coastal districts after start of rains. Situation farther S in Africa less clear, but adults seem to be sedentary, and younger birds most likely to move into new areas, but only one ringing recovery of individual more than 20 km from where ringed, and that had moved 47 km in a little over nine years. Vagrants recorded in S Algeria and once in S Libya.

Status and Conservation. Not globally threatened. Common and widespread, even locally abundant in low-lying, lusher parts of Africa. Common and widespread in lower-lying parts of Madagascar, and more thinly distributed on High Plateau. Distinctly localized or absent in mountainous or arid semi-desert and desert regions. In South Africa considered a minor pest, 17% of farms having a nest-destruction policy, and poison also used for controlling numbers of this species. On Kenyan coast, particularly about Mombassa, increasing population of *C. splendens* seems to be pushing out this corvid, which is harassed by mobbing behaviour of the smaller species. Its tolerance of humans and its omnivorous diet, however, should ensure a successful future for this crow.

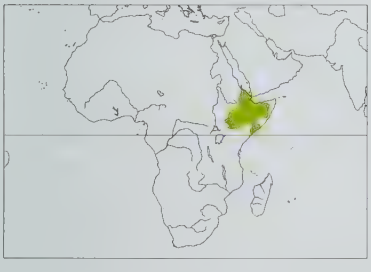
118. Ethiopian Raven



Corvus edithae

French: Corbeau d'Edith **German**: Somalirabe **Spanish**: Cuervo Etíope
Other common names: Dwarf/Somali Raven, Lesser Brown-necked Raven, Somali Crow

Taxonomy. *Corvus edithae* E. L. Phillips, 1895, Hainwaina Plain, Somalia.

Forms a superspecies with *C. albus* and *C. ruficollis*. Often treated as conspecific with latter, but close to former in size, structure and vocally. Hybridizes frequently with *C. albus* in SE Highlands of Ethiopia (and sporadic mixed pairs reported from most of range); recent observations suggest that interbreeding is not immediate when the two meet, and that some time is required for breeding-cycle synchrony to develop. Suggestion that present species is a population of all-dark *C. albus* considered unlikely, as some calls do differ and it replaces latter in the desert regions of the Horn of Africa. Monotypic.

Distribution. Eritrea, Djibouti, E & S Ethiopia, most of Somalia, extreme SE Sudan and N Kenya.

Descriptive notes. 46 cm; 435–450 g. Large corvid with tail of moderate length and distinctly graduated towards tip, stout bill and pointed throat feathers. Plumage black, glossed with green on crown and upperparts, gloss more violet on upperwing and tail; head and neck, including hindneck, dark glossy brown, duller and more blackish-brown when worn; feathers of throat and neck have white bases, those of rest of body are pale grey at base; underparts and underwing dull sooty black; iris dark brown; bill and legs black. Differs from *C. ruficollis* in smaller size and shorter bill, in flight by shorter wings and tail (and bill not regularly held pointing downwards). Sexes similar. Juvenile is duller and browner on head and body than adult. Hybrids with *C. albus* have pale or grey breast, or speckled breast and collar. Voice. Very similar to that of *C. albus*, usually a dry "wraaa" varying in pitch, becoming harsher and shriller in excitement; can be distinctly nasal and higher-pitched, reminiscent of call of *C. splendens*. Also has soft "wah-kah", second syllable rising in pitch, a winding double-note "korrrrh-karrrrh" and a husky "tschop". Various sounds uttered by feeding flock include brief clucking, clicking and gobbling sounds. Other transcriptions refer to a short, metallic "onk" or "kwonk", a double "rrawnk-rrawnk" and a flat "yack-yack".

Habitat. Open country, from deserts and bushy semi-deserts to dry savanna, and patchy cultivation, including coastal desert and inshore islands; in Kenya and Ethiopia exceptionally reaches 3000 m, but rarely above 2000 m and most numerous below 1100 m. Readily scavenges in villages and small towns.

Food and Feeding. Omnivorous. Diet probably similar to that of *C. albus*. Recorded items include carrion, small "animals", various invertebrates (insects and their larvae), ticks (Ixodoidea) and lice, and bird eggs; some plant material also taken, including grain. Forages on ground, alone, in pairs or in well spaced small flocks. Walks with ease, occasionally hops. Quite aggressive when in flocks, recorded as pointing bill skywards as a threat to approaching bird, which usually turns away. Outside breeding season, family parties gather into flocks of up to 100. Visits rubbish dumps, often boldly entering villages, sometimes with *C. albus*. Recorded as tearing into sacks to feed on grain; alights on camels to search for ectoparasites. Patrols seashore in search of carrion. Generally sociable at nocturnal roost, often in stands of palms, but said to prefer resting on ground by oasis (rather than in trees) for daytime roosting.

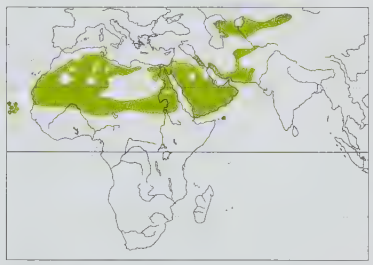
Breeding. Season chiefly Feb and May–Jun; eggs recorded Feb in Eritrea, Feb and May–Jun in Ethiopia, Mar–Jun (chiefly Apr and May) in Somalia, and Apr in Kenya. Pair-bond probably lifelong, and presumably monogamous. Solitary nester, with inter-nest distance 1·5–3 km; statements in older literature that this species nests in loose colonies not supported by modern observations. Nest, seemingly built by both sexes, a large untidy mass of sticks, cup lined with wool, feathers and plant fibres, usually placed in tree, more rarely on cliff ledge, in cave or on pylon or pole. Clutch 4–5 eggs, rarely 6; no information on incubation and nestling periods. Nest ocasionally parasitized by Great Spotted Cuckoo (*Clamator glandarius*).

Movements. Sedentary, as far as is known.

Status and Conservation. Not assessed. Probably not globally threatened. Common and widespread, but often somewhat localized. More field research required in order to determine population densities and precise relationship with *C. albus*. Its tolerance of humans and its scavenging habits should ensure a stable future, but interbreeding with the increasing and spreading *C. albus* could perhaps pose a threat in the long term.

Bibliography. Alamargot (1987), Ash (1983), Ash & Atkins (2009), Blair (1961), Britton (1980), Fry *et al.* (2000), Goodwin (1986), Hall & Moreau (1970), Jollie (1978a), Londei (1995, 2005, 2008), Mackworth-Praed & Grant (1960), Madge & Burn (1994), Meinertzhagen (1926), North (1962), Urban & Brown (1971), Wilson & Balcha (1989), Zimmerman *et al.* (1996, 1999).

119. Brown-necked Raven



Corvus ruficollis

French: Corbeau brun **German**: Wüstenrabe **Spanish**: Cuervo Desertícola
Other common names: Desert Raven

Taxonomy. *Corvus ruficollis* Lesson, 1831, Santiago, Cape Verde Islands.

Forms a superspecies with *C. albus* and *C. edithae*; often treated as conspecific with latter, but that is probably closer to *C. albus* (with which it regularly hybridizes). Isolated population on Socotra (consisting of birds of relatively large size) possibly worthy of subspecific status. Monotypic.

Distribution. Desert regions of C Asia, N Africa and Middle East: S & C Kazakhstan S in plains to Turkmenistan and probably SW Tajikistan; Cape Verde Is; from S Morocco, Algeria (except N) and S Tunisia S to Mauritania and N Senegal, E to Libya (except N), N Mali, Burkina Faso, Niger, N Nigeria, C Chad, Egypt (including Sinai) and N & C Sudan; E Israel and W Jordan S throughout Arabian Peninsula, E through SE Syria, C & S Iraq and S & E Iran to SW Pakistan (Makran coast) and plains of N Afghanistan (probably also extreme SW Afghanistan, in Seistan); Socotra I (off NE Somalia).

Descriptive notes. 52–56 cm; 500–647 g. Large corvid with distinctly elongated and pointed throat hackles often slightly forked at tip. Plumage is mostly blackish, glossed dark green on crown and upperparts, glossed violet on upperwing and tail; nape, upper mantle, throat and side of neck shiny brown, glossed with bronze-purple; underparts sooty black, with violet gloss on breast and flanks; iris dark brown; bill and legs black. Distinguished from most races of *C. corax* mainly by smaller size, slimmer build, shorter throat hackles, slimmer bill, brown colour on head and neck, and in flight by narrower wings with more pointed wingtip. Sexes similar. Juvenile is less highly glossed than adult, with head and underparts duller greyish-black, becoming browner on flanks and belly. Voice. Typical call a dry, flat "aarg-aarg-aarg" of varying intensity, often reminiscent of the "caw" of *C. frugilegus*. Several other calls include drawn-out "crrrarrh" and abrupt "cruk-cruk", latter softer and less resonant than the deep croak of *C. corax*.

Habitat. Semi-desert and desert plains, mountain foothills including desert cultivation, dry savanna and oases, desert settlements, rubbish dumps and army camps; also barren islands with some cultivation (Cape Verdes). Favours areas with desert shrubbery, e.g. tamarisk (*Tamarix*), saxaul (*Haloxylon*) and wormwood (*Artemisia*). Although preferring plains, it is widespread in the higher ground of Eastern Desert of Egypt, where reported as breeding at up to 2000 m. Tends usually to be replaced in mountains by *C. corax* in places where ranges meet, but in many areas (e.g. Iran and W India) latter inhabits desert plains, too.

Food and Feeding. Omnivorous; mainly carnivorous. Takes wide range of terrestrial invertebrates and vertebrates, from molluscs, locusts and crickets (Orthoptera), beetles (Coleoptera), caterpillars, termites (Isoptera), spiders (Araneae) and ticks (Ixodoidea) to small snakes, tortoises, lizards, birds and small mammals. Robs bird nests, even visiting mangroves of inshore islands to take eggs of Western Reef Egret (*Egretta gularis*); kills sickly newborn lambs and gazelles. Report of a flock chasing a hare (*Lepus*), flock-members trying to hit it with their feet. Patrols roads in search of roadkills and shorelines for frogs and dead fish. Scavenges about settlements and rubbish dumps. Searches for ectoparasites on neck and head of donkeys and camels, also pecks at and aggravates sores on animals. Joins vultures and other scavengers around slaughterhouses and carcasses. Takes a good deal of plant material such as maize, barley, grass seeds, dates, fruit and berries, also various human food scraps in villages. Captive bird seen to hide surplus food items. Digs in ground, and turns over stones and dung in search of grain and insect larvae; walks and hops confidently on ground. Seen to catch locusts in flight with feet; observed to work co-operatively, one or two birds acting as "beaters" to flush locusts into air, to be captured by other ravens. Forages alone and in pairs; non-breeders form larger gatherings, reaching as many as 1000 individuals at roosts on rare occasions (such numbers reported from Israel and Cape Verdes), but in C Asia gatherings of 100 considered notable. Roosts in trees by choice, also at times on cliff ledges and increasingly so on roadside wires and electricity pylons.

Breeding. Eggs reported mid-Mar to Jun in Turkmenistan, Dec–Mar in Arabia, Feb–Mar in Israel, Feb–Apr over most of N Africa, Dec–Mar in Sudan, Nov–Dec in Niger, Jul–Oct in Mali, Jan–Apr, Jun and again Sept–Dec in Mauritania, and mid-Nov to mid-Apr in Cape Verde Is; generally single-brooded, occasional reports of two broods possibly referable to replacements after failure. Monogamous, with long-term, possibly lifelong pair-bond. Solitary nester; in Israel, average inter-nest distance 3·3 km, closest nests 1·2 km. Sometimes assisted by a helper (offspring from previous year). Nest built by both sexes, taking 5 days (in captivity), a bulky structure of branches, sticks and roots, cup lined with plant fibres, feathers, paper, wool, hair and cloth, usually at crown of tree, in treeless desert commonly on electricity pylon or telegraph pole, or even on ground among shrubby thickets (e.g. *Tamarix*), and disused building, pile of scrap metal or cliff ledge also used; often immediately beneath huge nest of Lappet-faced Vulture (*Torgos tracheliotus*) in Arabia; occasionally takes over old nest of raptor such as Long-legged Buzzard (*Buteo rufinus*) or Osprey (*Pandion haliaeetus*); nest-site may be used for many years. Clutch 1–7 eggs, usually 4–5, clutches smaller (2–3 eggs) in true desert environment (in N Africa, at least); incubation mostly or perhaps wholly by female, period 18–23 days; chicks fed and tended by both sexes, possibly sometimes also by a helper, nestling period 35–38 days; young fly strongly at 42–45 days, remain with parents for

several weeks before joining non-breeding roving flock. Age of maturity or first breeding not confirmed; stated to be in 2 years in Kazakhstan, but reported as 6 years for captives.
Movements. Sedentary in most of range. In C Asia, many from N populations of Kazakhstan move S in Oct, returning in Mar, although some remain as far N as L Balkhash all winter unless weather severely cold. Movements elsewhere less apparent, but marked passage towards both Sinai and Jordan reported at Eilat (S Israel) during Jul–Sept, with return Feb–Mar. In N Africa more sedentary, or movements not well understood, but reports of short-distance movements in Mali, Sudan and Mauritania, the last associated with onset of rains. Vagrants reported from Mediterranean coast of Israel, Canary Is, Gambia, NW Ethiopia, C Syria, SE Turkey and N Pakistan.
Status and Conservation. Not globally threatened. Widespread and common throughout extensive range. Reported as increasing in some areas owing to improved desert farming techniques; in Israel has increased dramatically since 1960s following proliferation of military camps and cultivation of desert. In Algeria seems to be spreading N; in Morocco uncommon and localized on arid plains to S of Atlas ranges. Few estimates of numbers made, but in Egypt population estimated at between 10,000 and 100,000 pairs; 500–1500 pairs estimated for United Arab Emirates, and in Israel considered to be several hundred pairs. Status in several countries requires clarification; in Syria suspected to be breeding in at least one area, and in Tajikistan believed to breed in SW, but confirmation required. The species is little known in Pakistan but common along Makran coast, with reports inland as far as Quetta in winter; in Afghanistan known with certainty only from arid plains around Andkhui (in extreme N), but highly likely also in Seistan (in SW). A pair of unknown origin probably nested c. 1990 on Gran Canaria, in Canary Is. No longer breeds in Bahrain. Clearly, this is a successful and adaptable species, although competition with *C. cornix* may restrict further range expansions in N Africa and the Middle East.

120. Common Raven

Corvus corax

French: Grand Corbeau **German**: Kolkrabe **Spanish**: Cuervo Grande
Other common names: (Northern Great Holarctic) Raven

Taxonomy. *Corvus Corax* Linnaeus, 1758, Sweden.
Recent molecular-genetic investigations suggest that this species consists of at least three groups that are currently taking relatively independent evolutionary paths. Little, if any, genetic exchange occurs between populations of Old World and New World, allowing these two groups to maintain slight, but distinctive genetic signatures, in addition to which those in Canary Is (samples from Fuerteventura I only) are morphologically and genetically distinct from other Old World ravens (apparently having diverged c. 650,000 years ago). Thus, population in Canary Is, those elsewhere in Old World, and those in New World appear sufficiently isolated today to evolve independently. In Old World, a variety of described morphological forms may have been especially distinct 1 million years ago, but today they intergrade extensively and do not have unique mitochrondrial signatures. Similar process appears to be reducing genetic diversity in New World, where two clades recognized in current samples of mitochrondrial DNA: "California clade" found throughout W USA and represents most individuals in Mojave Desert, and "Holarctic clade" (which occurs throughout Old World) identified from samples in N North America (Alaska, Canada, Maine and Greenland); ravens from the two clades co-exist in roughly equal proportions in large area of North America (including Washington and Idaho), and where mating patterns and clade identity known (temperate rainforests of Olympic Peninsula, in Washington state) intercladal pairing is common, suggesting substantial gene flow between clades and a shared current evolutionary trajectory. Existence of both clades in W North America suggests that ravens may have colonized North America at least twice. Initially, "California clade" and "Holarctic clade" diverged from each other c. 2 million years ago, perhaps as glacial advances pushed original population into S refugia, and these distinct "California clade" ravens remained isolated from other ("Holarctic clade") ravens for c. 1 million years; during this time their sister-taxon, *C. cryptoleucus*, evolved, these taxa differing by 1·75% to 1·8% (suggesting that they diverged 1·1–0·6 million years ago, well after the two clades of present species diverged). "Holarctic clade" may have reinvaded North America across Bering Strait in last 15,000 years in the company of humans and grey wolves (*Canis lupus*). Many races described on basis of clines in morphology (decrease in size from N and high-elevation portions of range to S and desert parts) and plumage (decrease in bluish gloss and less pronounced lanceolate throat plumes from N to S); nominate race grades into *laurencei* in C Europe, and into *kamtschaticus* in W Siberia and W Russia and S to Black Sea, Caucasus, N Iran and Kazakhstan. Eleven subspecies currently recognized.
Subspecies and Distribution.
C. c. principalis Ridgway, 1887 – Alaska E across ice-free portions of Canada to coasts of Greenland, S in USA to Pacific coast of Oregon and Washington and, in E, in Appalachian Mts S to N Georgia.
C. c. sinuatus Wagler, 1829 – Rocky Mts from SW Canada (British Columbia) S in E USA through Idaho, Montana, Utah and Colorado and through Great Plains, Great Basin and SW mountains, to mainland Mexico and Nicaragua.
C. c. clarionensis Rothschild & E. J. O. Hartert, 1902 – SE USA (N California) S through NW Mexico (Baja California, including Clarion I) and E through Mojave Desert.
C. c. varius Brünnich, 1764 – Iceland and Faroe Is.
C. c. corax Linnaeus, 1758 – NW Europe from British Is and Fennoscandia S through W & C Europe and E to C Siberia (R Yenisei).
C. c. kamtschaticus Dybowski, 1883 – Siberia E to Kamchatka, Commander Is and coastal regions of Sea of Okhotsk, S to N Mongolia, NE China, Sakhalin I, Kurils and N Japan (Hokkaido).
C. c. hispanus E. J. O. Hartert & O. Kleinschmidt, 1901 – Iberian Peninsula, Balearic Is, Corsica, Sardinia and Italy.
C. c. laurencei Hume, 1873 – E Greece and Cyprus E through Middle East to E Kazakhstan, W China (except mountains) and N India.
C. c. tibetanus Hodgson, 1849 – C Asia from Tien Shan and Pamirs S to Himalayas and W China mountains.
C. c. canariensis E. J. O. Hartert & O. Kleinschmidt, 1901 – Canary Is.
C. c. tingitanus Irby, 1874 – coastal regions of N Africa from Morocco (S to pre-Saharian Atlas) E to Egypt.
Descriptive notes. 58–69 cm; 585–2000 g. The largest corvid; large, powerful bill with nasal bristles covering half or less of exposed culmen, throat feathers long and lanceolate (especially on male) and erected during dominance displays; in flight, long, fairly broad wings with prominent fingers, especially long tail often spread to form diamond shape. Nominate race is black, with greenish gloss on head and tail, primaries and underparts, more bluish-purple gloss on upperparts and rest of wing; bases of neck feathers brownish-grey; plumage generally duller and browner, with less gloss, when worn; iris dark brown; bill and legs black. Distinguished from congeners mainly by large size and shaggy-looking throat, in flight mainly by tail shape. Sexes similar, male significantly larger than female. Juvenile is duller than adult, with less metallic sheen, lacks lanceolate throat plumes, has iris light blue, soon becoming grey; immature has wing and tail feathers dull and brownish; base of bill gradually turns from yellowish to black during first year, and tongue, gape and palate turn from red to mottled grey/black to fully black during first two years, depending on social status; dominant birds attain black mouth lining within 1 year, but subordinates may not obtain black lining for several years. Races differ mainly in size: *varius* is a large race, larger and less glossy than nominate, with bases of neck feathers whitish; *kamtschaticus* is larger than nominate, with clearly larger and thicker bill; *hispanus* has relatively short wings and more arched bill than nominate; *laurencei* is slightly larger than nominate, and often has worn, brown plumage on nape, mantle and throat; *tibetanus* is very large and highly glossy, with longest throat hackles; *tingitanus* is small, with very short, stout bill, long wings and short tail, short and less lanceolated throat plumes, has plumage glossy and "oily"; *canariensis* is similar to previous, but has distinct brownish plumage, bill perhaps somewhat smaller; *principalis* is very large, varying clinally (from massive in N of range to relatively large in NE & NW continental USA), has largest bill of all races; *sinuatus* is relatively small (except perhaps in farthest S of range), with short wing and tail, short and slender bill, and small feet and skull; *clarionensis* is smallest race in North America. Voice. Large repertoire of at least 20 distinct calls of known function, 79 call types distinguished spectrographically, many mimicked sounds, and numerous utterances of unknown meaning. At least some calls are learnt socially from mates, and especially from nearby (within 12 km) birds of same sex. Adults "caw" loudly and hoarsely, this deep-pitched croaking varying in pitch and intensity to convey caller's motivation. Territorial adults "quork" often in sequence ("quork-quork...quork-quork"), frequently during aerial rolls or dives in defence of territory; mated pairs frequently give loud, patterned knocking (like sound of two wood blocks rapped together) audible for several kilometres, likely serving to defend territory from long range. Loud, harmonically rich "hoots", "yells" or "honks" used by territorial adults to thwart intruding conspecifics. Adult female often gives knocking calls in sequences of 2, 3, 7 or more syllables when excited. Very rapid knocking ("rattling") by female often occurs during duets between mateds after territorial defence or during courtship; male and female often perch side by side, bend over and, as female spreads wings and rattles, male opens bill, fluffs throat feathers and moves head in choking motion while uttering quiet garble of clicks, hisses and gurgles and flashing nictitating membranes ("air call"). Pair responds to predators, especially near nest, with a series of staccato "cluck" calls while flying excitedly with rapid and shallow beats; somewhat similar "ku-uk-kuk" given by one raven pursuing another in aerial chase, attacking individual uttering this call as it closes in or dives at intruder. Adults give large variety of bell-like, hiccup, dripping "woo-woo", and "toot" calls of unknown function (may be regionally, locally or individually distinct); "growls", "whines" and "screams" common among jostling birds entering communal roost, and goose-like "honks" often given during morning departure. Juveniles and females beg in typical corvid fashion to be fed by their parents and mates. Juvenile food-begging calls change into "yells" of immatures, which given at sight of defended food ("haa") or as dominants approach food ("who"). Two immatures "trill" in escalating vocal bouts that can lead to physical fights. Soft, babbling renditions of full repertoire of sounds common, especially by lone immatures or those discovering new foods.
Habitat. Extreme habitat generalist, breeding throughout forested and open coastal, steppe, mountain, desert, tundra and cliff regions of Northern Hemisphere. Generally in more open habitat in S (typically shrublands and deserts) and N (shrublands and tundra) portions of range where cliffs, sparse trees, including Joshua trees (*Yucca brevifolia*) in Mojave Desert (SW USA), and human structures afford nest locations; generally in coniferous and broadleaf forests in middle latitudes, where tree-nesting often more common than cliff-nesting. Abundant in temperate (coniferous) rainforest along N Pacific coast of North America; historically common in all human settlements within range, but today frequents human refuse tips, patrols roadways and recreational sites (least so in NE USA), and inhabits rural farms and settlements, small towns, and a few large cities. In W North America abundant in Anchorage (Alaska) and locally abundant in coastal and most natural habitats in Los Angeles, Riverside, San Diego and San Francisco (California metropolitan areas). Generally rare in large cities throughout rest of range, with some exceptions (e.g. Ulaanbaatar, Mongolia). Some avoidance of urban areas may reflect unsuitable habitat, abundant competitors such as gulls (Laridae) and other corvids, recent and extensive devastation, and historical persecution.
Food and Feeding. Opportunistic scavenger, historically closely associated with large carnivores, most notably wolves, and wasteful omnivores, notably humans. Eats huge variety of animals and plants. Preys on adult and nestling birds, eggs, small mammals (regularly young lagomorphs and occasionally adult lagomorphs and newborn lambs), sick and dying larger mammals (including sheep), toads, snakes, juvenile turtles, fish, and consumes invertebrates, notably Orthoptera, Lepidoptera, Coleoptera, craneflies (Tipulidae), ants (Formicidae), slugs, scorpions, earthworms, snails and diversity of marine invertebrates; scavenges garbage and slaughterhouse offal, dung, and nearly any kind of carrion, including sheep and cow placentas, discarded entrails of hunted animals, dead fish and whales, and road-killed mammals, birds and reptiles. Plant matter includes fruits, grains, berries, buds, and calcareous seaweed (*Corallina officinalis*); on some islands of Canary Is, fruit (especially *Opuntia* and *Ficus*) dominates diet. Predatory behaviour may result in significant local reductions in nesting success of colonial-nesting birds, also rare species such as desert tortoise (*Gopherus agassizii*). Locates food by sight, sound, perhaps also by olfaction at very close distances. Actively scans for carrion, investigates locations of gunshots, wolf howls, and calling conspecifics, watches foraging birds and mammals for cues; actively hunts from perch, in flight and on foot. Excessively cautious and wary around new foods. Where large animal carcasses a primary food, and when carcasses especially widely dispersed and ephemeral (e.g. in snowy N regions), naive ravens follow roostmates over many kilometres to newly discovered food bonanzas. Often roosts communally very close to semi-permanent food resources (e.g. rubbish dumps, residences offering continuous food supplements); wandering non-breeders the most frequent participants in winter roosts, and hence most apt to co-operate in sharing of information regarding food and other resources, these temporary groups of mostly unrelated and often different birds benefiting from sharing information because of increased food encounter rates and increased ability to procure foods defended by dominant breeding pairs. Breeding pairs often defend food discovered on their territory from single wanderers or small groups. Caches a variety of foods,

mostly on ground, at all times of the year; caching may be triggered by ephemeral or contested foods (under controlled experiments, ravens do not cache when food continuously available), but seen to cache from landfills where food (albeit of varying quality) continuously available; eggs may be cached whole and placed in micro-sites suitable for long-term storage; large or scattered items may be prepared away from cache site to reduce transportation costs (e.g. strips of meat and individual crackers collected to make a single load, which then carried to cache site). Combats cache raiders by sneaking out of view to cache, making false caches, and moving caches from locations perceived to be known to others.

Breeding. Breeds early in the year when snow often blankets the ground. Laying from late Feb in most of range, earlier in some areas, e.g. Dec in far S, and later in far N and at higher altitudes, e.g. mid-Apr in Greenland, N Siberia and W Chinese mountains; double-brooding rare (once case known in USA, at Riverside, in California). Socially monogamous, with pair-bond probably lifelong; occasional extra-pair copulations observed. In most situations, pair inhabits all-purpose home range throughout year. Defended space within home range poorly understood, but territory and defence of it is apparently restricted to area within 1–5 km of nest; defence involves vigorous chases of intruders accompanied by loud vocalizations, and physical attack with bill and feet if intruder caught. Both sexes procure nest material, but female appears to do most of construction work, especially shaping nest bowl, nest construction taking 1–3 weeks; a large and bulky platform 40–153 cm in diameter and 20–61 cm tall, made from dead sticks (25–150 cm long, 0·5–3 cm in diameter), lined with fine roots, grass, string and other bits of rubbish, and with mammal fur to make an inner cup 22–30 cm in diameter and 13–15 cm deep; placed 3–30 m up in stout, lower branches of tree (often few substantial branches below nest), or 5–30 m or more above ground on upper third of steep cliff (often well protected beneath overhanging block or ledge, in crack or in small cave), or up to 46 m high on artificial structure such as utility pole building, sign, radio tower, abandoned vehicle, oil derrick, bridge, irrigation pipe or windmill; sometimes old nest refurbished and reused. Clutch 1–8 eggs, typically 4–6; incubation by female, male occasionally assisting, period 20–25 days; hatching asynchronous, chicks brooded and fed by both parents, nestling period 4–7 weeks; fledglings remain with parents for a few weeks to several months, typically leave natal territory by late summer. Average brood sizes in most areas (Britain, Ireland, W USA) 2·5–3·6 young per nest, but slightly larger averages of 3·8 and 4·2 recorded in Utah and Oregon; lowest fledging success on Olympic Peninsula (Washington, in W USA), where 35 pairs fledged average of 1·2 young per nest, average elsewhere in North America and Britain ranges from 1·7 to 3·1. Maximum recorded lifespan in the wild 13 years 4 months, and credible reports of captives living for 40–80 years; survival during first year variable, 38% to 74%, likely dependent on vulnerability to mammalian predators shortly after fledging, and annual survival of breeders can be lower than expected on basis of body size (e.g. on Olympic Peninsula average 68·2% and in Mojave average 87%).

Movements. Relatively sedentary. Breeders may fly up to 30 km from nest to predictable food sources and travel throughout 12–1950 km² home ranges. Non-breeders less sedentary, ranging widely and nomadically over 1200 km² to more than 1900 km² each winter among concentrated, but ephemeral, food sources; may routinely travel 20–70 km one-way from communal roost to daily feeding locations. In Britain and most of North America, spends most of life within 50 km of natal site; in Britain, only four birds, all non-breeders in first two years of life, travelled more than 200 km from natal territory. Maximum distances between breeding and recovery sites include 551 km in Britain and 480 km in W USA (Oregon). In Greenland and other places above 60° N (or at extreme altitudes) considerably less sedentary; during winter, adults and juveniles from interior Greenland travel over 150 km to reach coast; one fledgling moved 811 km from Kangerlussuaq to S tip of Greenland in fewer than 146 days; another moved from N Greenland 1120 km to S.

Status and Conservation. Not globally threatened. Common to locally abundant. Occurs in widely distributed, low-density, and self-sustaining populations across most of its range; variation on this theme often directly related to past persecution or modern subsidizing by humans. In much of W North America and Europe populations expanding, often at alarming rates, because human activities provide food, water and nest-sites that increase reproduction and survival (especially of juveniles), and allow territories to become established far from natural sites (especially in open tundra and shrublands); in some of these situations populations locally extremely dense. Recent studies, however, reveal that some locally dense populations (W Mojave Desert) are maintained by immigration of non-breeders to locally abundant food subsidies; W Mojave Desert populations outside urban areas may not be demographically self-sustaining. In W Europe, this species was valued as a sanitary engineer in medieval cities, but widely persecuted from mid-1600s to mid-1900s or later. Wonder and appreciation were replaced with fear and apprehension as ravens were increasingly viewed as scavengers on the dead (including humans) and harbingers of evil. As a result, European populations were reduced, often to point of creating gaps in the species' distribution (e.g. throughout much N & C Europe). Persecution has been greatly reduced in most parts of Europe today (but continues in Iceland and Greenland) and this corvid is reclaiming former haunts, even in highly developed parts of London, Moscow, Berlin, Vienna and Warsaw. Active reintroduction efforts, in addition to reduced persecution and increased subsidization, have aided its return to parts of Germany, Netherlands and SE USA. Although general persecution reduced in recent times, increasing populations of this species in much of W USA have led to conflict and targeted killing campaigns. Increasing numbers often gather conspicuously at rubbish dumps, agricultural fields, desert water impoundments, and open-country petroleum development sites; this can bring them close to crops and sensitive wildlife species, and convince resource-managers and members of the public that control is necessary. For control of this corvid, managers are advised to integrate lethal control with behavioural modification and reduction in subsidies. To date, little has been done to reduce subsidies (engrained human attitudes difficult to change), but some landfills and artificial nest-sites have been retrofitted to reduce raven use; rather than removing subsidies, managers often simply opt to kill ravens. Large numbers have been shot and poisoned in California, Oregon, Utah and Nevada, with limited, local and short-term benefits to pistachios (*Pistacia*), Sage Grouse (*Centrocercus urophasianus*), the *browni* race of Least Tern (*Sterna antillarum*), Sandhill Cranes (*Grus canadensis*), desert tortoises, and Kentish Plovers (*Charadrius alexandrinus*). Lethal control may be ineffective, as removal of this corvid allows other generalist predators to increase, and wide-ranging ravens quickly recolonize areas when lethal control ends if food, water and nest subsidies not reduced. In addition, many lethal control efforts focus on concentrations of non-breeding individuals, leaving breeding population intact to fuel continued population growth.

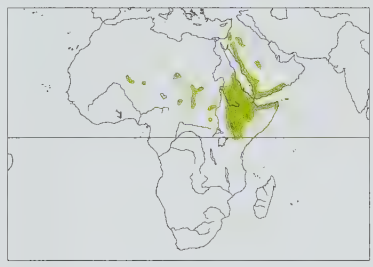
121. Fan-tailed Raven

Corvus rhipidurus

French: Corbeau à queue courte **German**: Borstenrabe **Spanish**: Cuervo Colicorto



Taxonomy. *Corvus rhipidurus* E. J. O. Hartert, 1918, Massaua, Eritrea.

Sometimes allocated its own monotypic genus, *Rhinocorax*. Certain morphological features, notably the nasal bristles and wing and tail shapes, indicate affinity with African ravens rather than N ones. Two subspecies recognized.

Subspecies and Distribution.

C. r. stanleyi Roselaar, 1993 – E Israel, Palestine and W Jordan, mountains of W & C Arabia (Hejaz and Asir Mts; Tuwaiq escarpment, Gebel Aja and Babel Sama) E into extreme W Oman.

C. r. rhipidurus E. J. O. Hartert, 1918 – E Mali (Adrar des Ipras and Homberi), NW Niger (Aïr Massif and Zinder), Chad (Tibesti and Kapka Mts and elsewhere), NE Central African Republic, highlands of Sudan (including Gebel Elba, on Egyptian border), most of Ethiopia and E to Eritrea, Djibouti and W Somalia, and E Uganda and N & W Kenya.

Descriptive notes. 46–47 cm; 512–734 g. An unmistakable crow-sized raven, wings projecting well beyond remarkably short tail (rounded at tip) when perched or on ground, relatively flat crown and small, quite stubby bill, nasal bristles fan-shaped and upcurving, concealing basal third of upper mandible, throat hackles slightly elongated, rather broad and forked at tip; in flight, extremely short tail and and broad-based wings, giving peculiar bat-like appearance. Plumage is black, with oily bluish-purple to dark green sheen, more brightly glossed in fresh plumage, duller but still black when plumage worn; feathers of throat and side of neck brownish-black with bronze sheen; feathers at side and near of neck have white bases, remainder have grey bases; underwing-coverts sooty black, contrasting with lighter underside of flight-feathers when seen overhead; iris dark brown; bill and legs black. Sexes similar, female distinctly smaller than male (obvious when the two seen together). Juvenile is similar to adult, but throat feathers shorter and more rounded, much less glossed, wing and tail feathers becoming browner through bleaching. Races differ only in size: *stanleyi* is c. 10% smaller than nominate. Voice. Typical call a far-carrying, rather high-pitched "craa-craa" or a downslurred "krroo-ah"; also gives prolonged guttural growling, which may vary in pitch. Variety of other calls, especially short conversational notes, may be given; sometimes strung together as a form of song composed of various clucks, squeals and bubbling sounds.

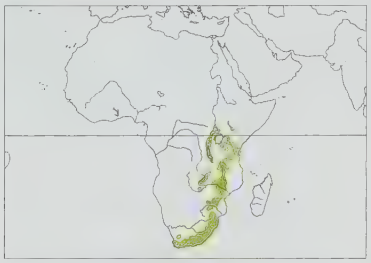
Habitat. Barren desert cliffs, gorges and canyons, from well below sea-level (Dead Sea) to 2400 m, rarely to 4000 m. Forages around desert settlements and oases.

Food and Feeding. Omnivorous. Eats grain, berries, dates, insects and other invertebrates; occasionally robs nests of other birds, taking both eggs and nestlings. Scavenges about human habitation, waiting on rooftops for scraps and waste to be discarded. Picks grain from animal droppings; catches locusts (Acrididae) in flight with its feet. Rides on backs of goats and camels, searching diligently for ectoparasites, pulling out tufts of hair in the process. Reported as hammering ping-pong ball with a stone (a rare instance of tool-using by a bird). Drinks frequently. While on ground, often holds bill partially open as if panting, giving impression that bill thicker than it really is. Feeds chiefly about desert cultivation, settlements and oases; foraging flocks in fields can give impression like that of a *C. frugilegus* flock. Spends most of time in the air, soaring and tumbling over cliff faces, making good use of thermals; at high elevations soars on thermals for considerable distances in search of food. Plays with sticks, feathers and the like, carrying them high and releasing them, then acrobatically dropping down to catch them again. Usually in pairs or small family parties, occasionally in larger gatherings at rubbish dumps and similar sites. Roosts in stands of palms by oases; roost of over 1000 reported in N Yemen in late Nov, having built up from 25 in early Sept. Roosts often mixed with *C. ruficollis*.

Breeding. Most data from Middle East, especially Israel. Eggs reported early Mar to late Apr in Israel, Dec–Jun (most mid-Feb to May) in Saudi Arabia, mid-Apr to early Jun in Sudan, Eritrea and Somalia, Feb–Mar, May–Jun and Sept in Ethiopia, Jan–Jun in Kenya and Jun in Niger. Monogamous, probably with long-term pair-bond. Typically solitary nester; exceptionally, 2–5 pairs nesting only 50–200 m apart on same ledge. Nest a flimsy structure of sticks, twigs and roots, cup lined with wool, hair and cloth, places usually in crevice or shaded ledge on sheer cliff face, extremely rarely in tree or on building. Clutch 2–6 eggs, usually 3–4; incubation period 18–20 days, nestling period 35–40 days; no information on roles of sexes. Nest occasionally parasitized by Great Spotted Cuckoo (*Clamator glandarius*).

Movements. Mainly sedentary. In winter at N limit of range in Israel and Jordan, dispersal S down Arava Valley towards Gulf of Aqaba; some dispersal of Arabian populations to lower-lying coastal regions from Tuwaiq escarpment and Dhofar during Sept–Mar. Reports of small parties and flocks (once over 1000 individuals) thermalling very high over N Yemen, often mixing with migrating raptors before returning; such occasions no doubt responsible for exceptional records of vagrants in Syria, SE Turkey, Upper Egypt and S Libya. African populations show little inclination of moving far, although the Libyan bird assumed to have wandered up from Tibesti (N Chad).

Status and Conservation. Not globally threatened. Locally common, even locally abundant (e.g. in Arabian Peninsula). Population in Israel estimated at 300 pairs, centred on cliffs and wadis flanking Dead Sea. No estimates from elsewhere, but locally common in Djibouti, Eritrea, Ethiopia, Sudan, Kenya and Chad; said to be rare in Mali, and status in Central African Republic uncertain, based on one record in NE of country. Until recently a few pairs nested in mountains of Sinai (NE Egypt), but now only a few individuals turn up there in winter. Believed to have declined in Israel over recent decades through competition with steadily increasing population of *C. ruficollis*. Protected at a number of nature reserves in Israel and national parks in some of the African coun-



tries in which it is found. In parts of Saudi Arabia has become a local nuisance to date-farmers, who cover their ripening fruit with sacking to protect the crop from the ravens.

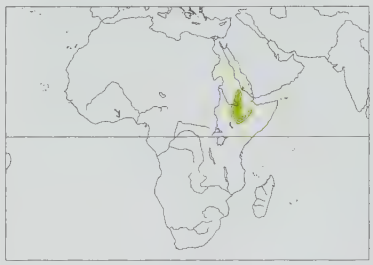
122. White-necked Raven

Corvus albicollis

French: Corbeau à nuque blanche **German**: Geierrabe **Spanish**: Cuervo Cuelliblanco
Other common names: Cape/White-naped Raven, African White-necked Raven

Taxonomy. *Corvus albicollis* Latham, 1790, Great Namaqualand, South Africa.
Forms a species-pair with *C. crassirostris*, the two sometimes placed in a separate genus, *Corvultur*. Monotypic.
Distribution. Uganda and W Kenya S over E DRCongo, Rwanda, Burundi, Tanzania, Zambia, Malawi, N & W Mozambique, most of Zimbabwe (except W), E & S South Africa (S to Cape Town), Swaziland and Lesotho.



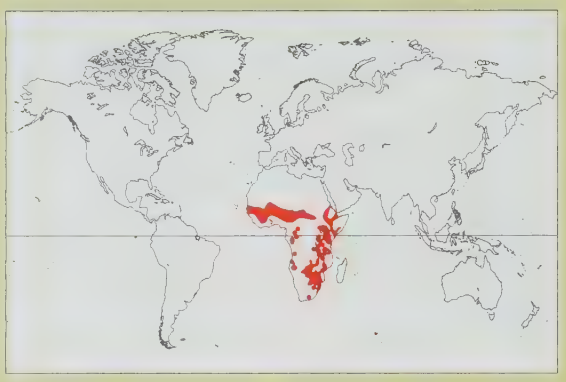
Descriptive notes. 50–56 cm; 762–1157 g. An unmistakable very large, chunky raven with relatively short tail and broad-based wings; nasal bristles fan-shaped, upcurving, almost concealing basal third of upper mandible, throat feathers pointed and slightly forked; massive bill with strongly arching culmen, making bird appear front-heavy in flight. Head, neck and underparts are blackish-brown with purplish sheen, lores blacker; large white patch across lower nape and upper mantle, extending slightly onto side of neck; feathers of foreneck and breast often fringed whitish, forming weak breastband; remainder of plumage, including wings and tail, coal-black with green sheen (this sheen is lost through wear, and plumage then becomes overall dull brownish in tone); iris dark brown; bill black, ivory-white tip; legs black. Sexes similar. Juvenile lacks white tip of bill, is duller than adult, often with some dark streaking in white nape patch, and sometimes with scattered white feathers over neck and breast. Voice. Typical call a surprisingly high-pitched, short, rolled "kraa" or longer "krrraaa", often uttered without rolling quality (then sounding like bleat of a trumpet). Also reported is a short metallic clattering "cluk-cluk-cluk", directed, with head bowed, at presumed mate.
Habitat. Inhabits hilly and mountainous country, occurring in less barren habitats than *C. rhipidurus*. Patrols over grassland, rugged hills, gorges and open hill forest. Chiefly found between 1000 m and 3000 m, but down to sea-level in South Africa and recorded up to 5800 m in N Tanzania (Mt Kilimanjaro).
Food and Feeding. Omnivorous, but mainly carnivorous. Takes wide range of invertebrates and vertebrates, from locusts (Acrididae), beetles (Coleoptera), caterpillars, beetle larvae and ticks (Ixodoidea) to small tortoises, lizards, snakes, small birds and small mammals. Robs bird nests, taking both eggs and nestlings, even eggs of Verreaux's Eagle (*Aquila verreauxii*), as well as those of domestic chickens and geese; also kills sickly newborn lambs. One in S Kenya seen to glide down from tree, snatch a Superb Starling (*Lamprotornis superbus*), hold it in one foot, and peck repeatedly at its head; it then plucked some head feathers from starling, but stopped and half-covered the victim with grass and earth, before leaving; raven returned later and immediately retrieved the starling, severed the head, and buried the rest under a grass clump; it returned several more times, each time eating just a few morsels from the carcass. Patrols roads in search of roadkills and lakeshores for frogs and dead fish. Scavenges about settlements and rubbish dumps, becoming very bold and confiding where unmolested; reported as stealing and swallowing bar of soap at a camp. Searches for ectoparasites on backs of cattle, and reported as carrying small tortoises high up and dropping them on to rocky ground to break the shell. Eats some plant material, such as maize, peanuts, fruit and berries, and seen to take a honeycomb and various human food scraps from camps and villages. Forages chiefly on ground, walking with bold swaggering gait and rather upright carriage, hopping or side-stepping with agility. Will feed inside tree canopy, picking insects from among foliage. Typically forages alone or in pairs, but large gatherings of up to 150 individuals reported on occasion, and exceptionally 800; such flocks largely non-breeders and quite nomadic by nature. Like *C. rhipidurus* spends much of day in thermalling high, often with vultures, and enjoys "playing", swooping and diving over cliff faces, dropping sticks and small stones and catching them again, often somersaulting (wind then producing loud swishing or whining sound through the primaries) before catching item again, or allowing partner to catch and pass it. Roosts communally on cliffs in gatherings of up to 40, rarely several hundred.
Breeding. Eggs reported Oct–Dec in Kenya, Aug–Oct in Uganda, Feb in DRCongo, Oct in Tanzania, Sept–Nov in Malawi, Sept in Zambia and Zimbabwe, and Aug–Dec in South Africa. Monogamous, with long-term pair-bond; partners of one pair known to have been together for 14 years. Solitary breeder. Nest a large platform of twigs and sticks, deep cup lined with wool, grass, rags, feathers and hair, mostly c. 30 m from ground and usually in crevice or on ledge of sheer cliff face, extremely rarely in tree. Clutch 2–7 eggs, usually 4; incubation believed by female alone, period 19–21 days; chicks fed mostly by female by regurgitation, male may attend but rarely helps, nestling period 21–28 days; young remain with parents until up to a few weeks of start of next breeding season. In S of range, averaged of 2 young fledged per nest.
Movements. Chiefly sedentary, but large flocks of non-breeders become semi-nomadic and wander throughout non-breeding season. Vagrants have turned up in Botswana and in N Kruger National Park (South Africa); wandering individuals recorded in SW Namibia and vagrant reached SW Sudan.
Status and Conservation. Not globally threatened. Locally common; numerous reports of non-breeding flocks suggest even locally abundant. No population estimates. Considered a pest in parts of South Africa and elsewhere because of its sheep-killing habits, and is widely trapped, poisoned or shot and its nests destroyed by farmers. Marked decrease reported in extreme N part of range in Kenya as a result of eating poisoned carcasses put out for predators of cattle and sheep.
Bibliography. Britton (1980), Chapin (1954), Cyrus & Robson (1980), Fry *et al.* (2000), Goodwin (1986), Hall & Moreau (1970), Harrison *et al.* (1997), Hockey *et al.* (2005), Irwin (1981), Jackson *et al.* (2001), Lewis (1989), Lewis & Pomeroy (1989), Mackie & Landman (1982), Mackworth-Praed & Grant (1960, 1973), Maclean (1993), Madge & Burn (1994), Meinertzhagen (1926), Parry (1981), Sinclair *et al.* (1993), Tarboton *et al.* (1987), Uys (1966), Winterbottom (1975), Zimmerman *et al.* (1996, 1999).

123. Thick-billed Raven

Corvus crassirostris

French: Corbeau corbivau **German**: Erzrabe **Spanish**: Cuervo Picogordo

Taxonomy. *Corvus crassirostris* Rüppell, 1836, Halai, Eritrea.
Forms a species pair with *C. albicollis*, the two sometimes placed in a separate genus, *Corvultur*. Monotypic.
Distribution. Highlands of Eritrea and Ethiopia.



Descriptive notes. 60–64 cm; one bird 1135 g. An unmistakable very large raven with relatively long, wedge-shaped tail, and disproportionately massive bill with strongly arching culmen, making bird appear front-heavy and almost hornbill-like in flight; feathers of head very short and dense, those of throat short and rounded, nasal bristles relatively shorter than in *C. albicollis*, upcurving, but not reaching culmen ridge. Plumage is almost wholly black, upperparts with blue or purple-blue gloss, underparts duller black; throat and side of neck brownish-black; relatively large white patch on upper nape extending in white line down centre of nape; iris dark brown; bill black, ivory-white tip; legs black. Sexes similar. Juvenile lacks white tip of bill, is duller, more sooty brown, than adult, with culmen ridge less highly arched. Voice. Most calls remarkably high-pitched for one of the world's biggest corvids. Typical call a scraping bubbling sound, also a low, guttural wheezy croak. Also gives deep pig-like grunt, "urrrk" or "grrrarrr", and a double "harr-harrr" cough.
Habitat. Frequents both open and forested mountainous country, especially with escarpments and sheer cliffs; also cultivations, lakeshores (equally at home by fishermen's landing stages with large trees nearby), and even towns and cities (including Addis Ababa) so long as large trees present. Found between 1200 m and 4100 m, mainly 1500–3000 m.
Food and Feeding. Carnivorous, but some plant material taken. Diet includes locusts (Acrididae) and beetle larvae (Coleoptera), caterpillars, lizards, snakes, small birds and small mammals. Robs bird nests, taking both eggs and nestlings. A true scavenger, becoming quite fearless when living near human habitation; by some Rift Valley lakes attends fishing boats offloading catches on shore, shoulder to shoulder with scavenging Marabous (*Leptoptilos crumeniferus*) and Hamerkops (*Scopus umbretta*). Joins vultures to feed on carcasses, vultures appearing to give way to it (and seeming in awe of its massive bill); steals bones dropped by Bearded Vultures (*Gypaetus barbatus*). Digs out mole-rats (Bathyergidae) from high alpine moorland, and other rodents from grassland. Scatters dung to get at insects and grain, virtually turning head upside-down while executing the scattering movements. Digs planted grain from fields, sometimes causing minor damage to crops. Feeds chiefly on ground, walking with bold swaggering gait and rather upright carriage, hopping or side-stepping with agility. Lifts head to make bill more imposing (vultures give way at carcass even if merely approached by raven with bill held towards them). Will also feed inside tree canopy, picking insects and berries from among foliage. A captive individual habitually hid surplus food items. Typically forages alone or in pairs, and less likely to form large gatherings than is *C. albicollis*; groups of more than ten individuals unusual. Soars on thermals and enjoys aerobatics, playing with sticks. Roosts in well-leaved large tree, normally in pairs or family groups.
Breeding. Eggs reported Dec–Apr in Ethiopia; occasionally double-brooded. Long-term pair-bond. Solitary breeder. Nest a very large platform of branches and sticks, with hollowed area on top lined with rags, coarse hair, grass, wool, string and the like, placed c. 15–20 m above ground at junction or crossing of strong branches in large tree, more rarely on cliff ledge. Clutch 4 eggs; no information on incubation and fledging periods; young remain with parents for several months after leaving nest.
Movements. Primarily sedentary; wanderers recorded in E Sudan (Famaka and Galabit), in NW Somalia (Ban Seila), and in Moyale district of S Ethiopia close to Kenyan border.
Status and Conservation. Not globally threatened. Locally common, perhaps even locally abundant. No population estimates. Widespread in W & SE Highlands of Ethiopia S to Sidamo, and in Eritrea in highlands E of Asmara and S highlands. Adaptable and opportunistic; widely recorded in a range of habitats, from montane grassland and alpine moorland to open forest, city parks and large gardens.
Bibliography. Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family BUPHAGIDAE (OXPECKERS)

- Medium-sized passerines with heavy, laterally flattened bill; plumage dull brownish and buff, with contrastingly bright eye wattle and bill.
- 20 cm.

- Africa.
- Savanna and farmland with large ungulates.
- 1 genus, 2 species, 3 taxa.
- No species threatened; none extinct since 1600.

Systematics

The name Buphaginae, as a subfamily within the starling family (Sturnidae), was introduced by the French ornithologist R. P. Lesson in 1828. This placement of the oxpeckers was followed by G. R. Gray, R. B. Sharpe and A. Reichenow, whereas W. L. Sclater placed the starlings and the oxpeckers in a single family without further comment. Subsequently, D. Amadon noted that the oxpeckers were so aberrant that their membership of the Sturnidae was questionable, and he cited only "the wing structure and other morphological resemblances, the harsh, unpleasant calls, and the habit of nesting in holes of trees" as characters common to the two groups; these features, however, clearly do not constitute strong evidence of a relationship in a phylogenetic sense. Amadon later suggested merely that they were "probably of common ancestry with other starlings", and in 1962, in J. L. Peters's *Check-list of Birds of the World*, he retained them as a subfamily of the starlings. Almost 20 years later, H. E. Wolters, in his treatment of the Sturnidae, placed the two *Buphagus* species first, followed by the monotypic Asian starling genus *Scissirostrum*, implying a primitive position within the family, but not in a separate subfamily. The melanin granules in the feathers were found, on microscopic investigation, to be round and solid, typical of the presumed "primitive" condition shared with many starling species, but also with other birds. The karyotype of the Red-billed Oxpecker (*Buphagus erythrorhynchus*) resembled that of several *Sturnus* species, but no detailed comparisons were made with members of other bird families. C. G. Sibley and J. E. Ahlquist, in their phylogenetic analyses based on DNA–DNA hybridization, did not include *Buphagus* among the species that they examined, and Sibley and B. L. Monroe, in their 1990 checklist, placed the oxpeckers closest to the genus *Scissirostrum* in the tribe Sturnini, evidently influenced by morphological similarities.

Some authors, such as P. A. Clancey, have preferred to recognize a separate family, Buphagidae, and this decision, published in Clancey's 1980 checklist of southern African birds, was followed by most southern African authors until the most recent revision of *Roberts Birds of Southern Africa*, in 2005, which incorporated *Buphagus* in the Sturnidae. For the rest of Africa, the oxpeckers were generally retained in the family Sturnidae following the checklist for East Africa, by P. L. Britton, and the Afrotropical list of R. J. Dowsett and A. D. Forbes-Watson; and C. J. Feare and A. J. F. K. Craig included the two oxpecker species in their monograph of the starling family, a decision based on a preliminary phylogeny of the African genera that utilized the available morphological and biological characters. Nevertheless, volume VI of the major avifauna *The Birds of Africa*, published in 2000, accorded the oxpeckers full family rank, as the Buphagidae. No new data were produced in support of any of these decisions.

Three independent molecular phylogenies have now placed the oxpeckers as basal to a group which includes the mockingbirds (Mimidae) and the starlings. The consensus view is to assign separate family rank to each of the three groups. A tentative date for the divergence of the Buphagidae, based on a molecular clock, is 22 million years ago, but there are at present no known fossils which could provide independent confirmation of the age

Oxpeckers spend most of the day perched on large mammals. The arrangement of their leg muscles resembles that of starlings (Sturnidae), the only differences affecting muscles that increase the grasping power of the feet. The bill of the ***Red-billed Oxpecker*** *is laterally flattened and slightly bulbous towards the centre, and is bright red in the adult. That of the Yellow-billed Oxpecker* (Buphagus africanus) *is laterally flattened and bulbous towards the tip; the basal part of the bill is yellow, and the distal portion red. Nestlings of both species have a greenish-yellow bill, which changes to dark brown when they fledge. Adult bill colour is acquired at about seven months in the Red-billed Oxpecker.*

[*Buphagus erythrorhynchus*, Samburu National Park, Kenya. Photo: Theodoulos Poullis]

of the group. The two extant species are clearly sister-taxa, and hybrids between them have been reported from Zimbabwe in free-living populations in which one species greatly outnumbers the other. As with many other African birds, a plethora of subspecific taxa has been described, the great majority based on minor differences in size and plumage; most of these differences seem not to be biologically informative in terms of defining populations between which there is reduced gene flow.

Thus, the common ancestor of the oxpeckers and the starlings would have shown some of the morphological traits described above, which have been cited previously as evidence of relationship. In cladistic terms, however, these are shared primitive characters, and thus uninformative in comparison with derived features. In Africa, the savanna habitat has been the centre of evolution for a number of bird families, and also for the ungulates, so that there would have been a long association between the birds and the mammals. Several modern starlings include ectoparasites in their diet, and have been seen to remove ticks (Ixodoidea) from both domestic and wild ungulates. In the case of the Red-winged Starling (*Onychognathus morio*) and the Pale-winged Starling (*Onychognathus nabouroup*), a regular grooming association with the klipspringer (*Oreotragus oreotragus*) has been noted at several localities in Africa (see page 681). Dietary specialists could well have evolved from such opportunistic generalists.

Morphological Aspects

The plumage of oxpeckers is dull, lacking any of the iridescence displayed by the starlings, and there is no sexual dimorphism in coloration. Males of both species are, on average, slightly larger than the females, although considerable overlap in measurements exists. The tail is graduated, with the individual rectrices stiff and pointed, and it is used as a prop to support the bird in the posture of a woodpecker (Picidae) on a tree trunk. Indeed, an observer at a Red-billed Oxpecker nest in a tree-hole reported that, when one young left the nest prematurely and fluttered to the ground below, the adults led it back to the nest by running up the trunk in a manner reminiscent of a woodpecker. The moult is very protracted, the Red-billed Oxpecker taking more than 300 days to replace the primary remiges in South Africa. As a consequence, some overlap between breeding activity and moulting will occur, although, with such a slow rate of moult, this is unlikely to be stressful for the birds. On the evidence of museum specimens, an extended moult period is likely to be typical for all populations of both oxpecker species.

Although the two species differ in bill shape, the Yellow-billed Oxpecker (*Buphagus africanus*) having a flatter and deeper lower mandible than that of its congener, there is no clear evidence that this is associated with different feeding methods. Nestlings of both species have a greenish-yellow bill colour, which changes to dark brown when they fledge, and they have a yellow wattle around the eye, which darkens to dull brown in the immature. In the case of the Red-billed Oxpecker, the eye wattle changes again, to yellow, in the adult, although this is not so with the Yellow-billed Oxpecker. Juveniles younger than 60 days of age still have a yellow bill, while the bill of the young Red-billed Oxpecker becomes dark brown from about 60–120 days. Adult bill colour is acquired at about seven months by the Red-billed Oxpecker, and certainly within the first year of life by the Yellow-billed Oxpecker. Further, juveniles have a dark brown iris, which, in the case of the Red-billed Oxpecker, starts to turn yellow at about four months and changes to yellowish-red by the time the birds are 6–7 months old. The timing of this iris-colour change has not been recorded for the other species, and the pigments or tissue structures responsible for the eye coloration have not been described. The possible signal value of these changes in eye and bill colours has yet to be studied. J. P. Chapin reported that the eye colour of a captive oxpecker varied, and he speculated that it might be dependent on blood flow, in which case spontaneous changes in the intensity of eye coloration would be possible. Bird-ringers have reported and photographed dramatic changes in iris colour from red to yellow and back again, sometimes affecting the eye on one side only. In the Yellow-billed Oxpecker the iris has a narrow yellow inner ring, a broad red band, and a very narrow outer yellow ring; here too, shifts in iris colour from yellow to orange and red have been noted in birds in the hand. This strongly suggests that under natural conditions also, changes in eye coloration may accompany behavioural interactions between the birds, and observers should be alert to this in the field.

P. R. Lowe commented that his dissection of the jaw musculature of *Buphagus* suggested that the latter was a starling in the broad sense, but that the maxillo-palatine and vomer bones in the

Both species of oxpecker have dull plumage, with none of the iridescence of the starlings. Sexes are alike. Juveniles of both species have plumage like adults, and yellow wattles round the eye, which darken to dull brown in the immature. In the ***Yellow-billed Oxpecker****, the wattle remains brown, but in the Red-billed Oxpecker* (Buphagus erythrorhynchus) *it changes again to yellow in the adult. Three independent molecular phylogenies have placed the oxpeckers as basal to a group which includes the mockingbirds (Mimidae) and starlings. The consensus is to assign family rank to each of the three groups. The Buphagidae may have diverged around 22 million years ago, but this is based on a molecular clock.*

[*Buphagus africanus africanus*, Serengeti National Park, Tanzania. Photo: Konrad Wothe]

*The **Red-billed Oxpecker** forages in small groups, and up to 15–20 individuals have been seen on a single giraffe* (Giraffa camelopardalis). *Sometimes both species of oxpecker are found feeding on the same host mammal. In the evening, Red-billed Oxpeckers fly off to roost in trees or reedbeds, in small groups, or in large flocks made up of birds from a wider area. Similar behaviour has been reported for Yellow-billed Oxpeckers* (Buphagus africanus) *in Nigeria, although elsewhere this species has been observed sleeping while perched on its host mammal.*

[*Buphagus erythrorhynchus*, Nylsvlei Nature Reserve, South Africa. Photo: Hugh Chittenden]

skull differed sufficiently from those of other starlings to imply that it should be placed in a separate subfamily. W. J. Beecher also examined the jaw muscles of the starlings, and noted that, in the Red-billed Oxpecker, both the protractor of the quadrate and the pterygoid and palatine muscles were enlarged, a development typical of the woodpeckers and apparently associated with the buffering of the brain against the shocks resulting from blows delivered by the bill. In other respects, he found the jaw musculature to be similar to that of the primitive starling condition, as opposed to the derived state found in those starling species that are specialized for probing.

Oxpeckers spend most of the day perched on the top or side of large mammals (see General Habits), and the leg musculature reflects this. Studies of the hind-limb musculature of the oxpeckers showed that the basic arrangement of the leg muscles resembled that of true starlings, the only differences affecting muscles which increased the grasping power of the feet. The legs are relatively short compared with those of either perching or ground-dwelling birds of similar body weight. The claws of oxpeckers exhibit the structure and curvature typical of climbing birds such as woodpeckers, treecreepers (Certhiidae) and nuthatches (Sittidae), whereas the Common Starling (*Sturnus vulgaris*) has the claws of a typical perching bird. In contrast to members of the starling family, the oxpeckers' hind claw is shorter than the claw on the middle toe, the reverse of the pattern found in perching birds. Oxpeckers also have a very fine constricted tip on the claws, which may be an adaptation for penetrating the substrate at the tip while maintaining claw strength along the rest of its length. One collector commented that, if a freshly killed oxpecker was placed on the skin of an ox, the feet and claws immediately grasped the substrate, and it was difficult to disengage them.

Habitat

Both members of this family are savanna species, being absent from deserts and from closed evergreen forest. Their habitat choice, however, is further constrained by preferences for particular host mammals, and for the main tick species on which they feed. The favoured ticks are limited by humidity, and evidently cannot survive in some open grassland or scrub habitats; these regions would also lack suitable nesting sites for the oxpeckers. In South Africa, C. J. Stutterheim showed that the historical records of the Red-billed Oxpecker coincided closely with the distribution of the two commonest tick species, namely *Boophilus decoloratus* and *Rhipicephalus appendiculatus*, recorded in the stomach contents of wild birds, and favoured in feeding trials with two captive individuals. Both of these tick species, however, extended into the winter-rainfall region of the southern coast, whereas the western limit for the Red-billed Oxpecker was at the boundary of the summer-rainfall region.

The Yellow-billed Oxpecker, too, feeds extensively on *R. appendiculatus*, with ticks of the genus *Amblyomma* apparently its second choice. The ticks are again a good predictor of this oxpecker's distribution in north-eastern South Africa, but this buphagid seems never to have occurred so far south as its congener. For other regions of Africa, data on tick distribution are too incomplete for any correlation with the distribution of the birds to be assessed. Through much of eastern Africa the two species are extensively sympatric, and there is no obvious separation between them in habitat selection; both have been recorded at up to 3000 m in Kenya, with some indication that Yellow-billed Oxpeckers are more often found above 1000 m and Red-billed Oxpeckers at lower altitudes.

Considerable overlap in host choice between the two oxpecker species is evident, and the two can sometimes be seen side by side on the same mammal. There have been no systematic observations of their interactions in this situation, although there is little indication that either of the two buphagid species is influenced in its choice of host animal by the presence of the other species. Under captive conditions, Yellow-billed Oxpeckers were constantly dominant over Red-billed Oxpeckers, although there were relatively few direct confrontations. Some mammal species appear to be avoided. African elephants (*Loxodonta africana*) do not tolerate oxpeckers and quickly chase them off. A few reports from Zimbabwe of oxpeckers on elephants were during a severe drought, when the elephants were in very poor physical condition and appeared totally indifferent to the presence of the birds.

The vocalizations for which both oxpecker species are most renowned are their alarm calls, and indeed no song has been described for the ***Yellow-billed Oxpecker****. The hissing "kriss kriss" of this species alerts its hosts to potential threats. This call, and the buzzing flight call, are the diagnostic vocalizations for observers in the field. In the early twentieth century, observers reported that oxpeckers seemed disconcerted by the failure of domestic cattle to react to their alarm calls. Forty years later, their behaviour had changed: the birds moved to the sides of cattle furthest from the approaching human, but did not give alarm calls, although not far away, oxpeckers on wild game immediately gave alarm calls when approached.*

[*Buphagus africanus africanus*, Masai Mara National Park, Kenya. Photo: AGE/ www.photolibrary.com]

It has been suggested by several observers that elephants are sensitive to the sharp claws of oxpeckers, one ornithologist describing them as being thin-skinned animals with a trunk. On the other hand, through much of western Africa, elephants are commonly seen with Piapiacs (*Ptilostomus afer*), a corvid having much blunter claws and a different foot structure, perched on them. Bushbucks (*Tragelaphus scriptus*) and common waterbucks (*Kobus ellipsyprimnus*) have been seen actively to dislodge oxpeckers which landed on them; lechwe (*Kobus leche*) and puku (*Kobus vardonii*) are not exploited by the birds, nor are southern reedbucks (*Redunca arundinum*). The impala (*Aepyceros melampus*) seems to be the only smaller antelope regularly patronized by oxpeckers, whereas there are no reports for any of the duikers (Cephalophinae). This may be explained by the fact that impalas are found in bushy habitat, which leads to a high load of immature ticks; and live in a herd structure, which provides a number of individual hosts close together. In Zambia, the large-bodied Lichtenstein's hartebeest (*Alcelaphus lichtensteinii*) seemed to be avoided by oxpeckers, although it was reported as a host for Yellow-billed Oxpeckers in Mali, while the tsessebe, or topi (*Damaliscus lunatus*), is also utilized much less frequently than would be expected.

Many observers have provided lists of the host mammals on which oxpeckers have been sighted. In current national parks these may often be biased by the availability and relative abundance of particular game species, and this may account for some of the apparent regional differences observed. Nevertheless, there is a general consensus concerning the ungulates which are utilized most frequently under natural conditions. These are the African buffalo (*Syncerus caffer*), white rhinoceros (*Ceratotherium simum*), black rhinoceros (*Diceros bicornis*), giraffe (*Giraffa camelopardalis*), hippopotamus (*Hippopotamus amphibius*), greater kudu (*Tragelaphus strepsiceros*), eland (*Taurotragus oryx*), roan antelope (*Hippotragus equinus*), sable antelope (*Hippotragus niger*), Burchell's zebra (*Equus burchellii*), blue wildebeest (*Connochaetes taurinus*), impala, and warthog (*Phacochoerus aethiopicus*).

Cattle arrived in North Africa at least 8000 years ago, and there were certainly herds of domestic animals north of the equator for thousands of years, although the herdsmen are thought to have moved southwards only some 2500 years ago, reaching the current southern limit of the oxpeckers' distribution about 2000 years before the present. Today, cattle are the primary hosts of oxpeckers in many regions. G. F. Archer noted that oxpeckers were rare in Somalia not only because of the general absence of wild ungulate hosts, but also because of the widespread replacement of cattle and donkeys by camels (*Camelus*), which were evidently not favoured by the buphagids. Single-humped domesticated camels, known as dromedaries (*Camelus dromedarius*), are thought to have reached Africa from Asia only within the last 1000 years. Nevertheless, some observers do report instances of oxpeckers feeding from camels. Horses will usually not tolerate oxpeckers according to some observers, but others have reported these birds perching on horses, often feeding at wounds, as well as on donkeys and mules. Oxpeckers occasionally perch on goats or sheep, and sometimes on domestic pigs.

General Habits

Since oxpeckers spend most of their days perched on the host mammals, relatively few activities take place away from the host. Nevertheless, oxpeckers have been observed to dust-bathe, as well as indulging in conventional bathing in water. The birds will leave their mammalian hosts briefly and fly to water-holes in order to drink or bathe, but more often they are passengers when the mammals go to drink. Sometimes the oxpeckers simply run down the animal's leg to reach the water, and take a few sips without actually "detaching" themselves from the mammal. After bathing, they preen the wet plumage while perched on the host. In addition, captive Red-billed Oxpeckers adopted typical sun-bathing postures while perched on a wall within their enclosure, and they were also photographed while sunning, with the wings and tail spread out, on the back of a rhinoceros.

When moving about on the host mammal, oxpeckers generally hop, moving both hind limbs simultaneously, but when stalking flies or during courtship they will also "walk", moving the limbs alternately. They seem invariably to hold the head up, and

they move forwards or sideways and even backwards, but seldom hang suspended underneath the animal. When defecating, oxpeckers lean forward, raise the tail, and generally spray the excrement well away from the host's body.

Throughout their range, Red-billed Oxpeckers leave the host animals in the evening and fly off, as small groups, or as large flocks from several sites, to roost in trees or reedbeds. These roost-sites may be shared with *Lamprotornis* starlings, and in some areas even buildings are used for roosting. Similar behaviour has been reported for Yellow-billed Oxpeckers in Nigeria, where the birds roosted in trees, but in Zambia this species was seen to sleep on buffaloes at night, in Zimbabwe observers reported the oxpeckers sleeping while perched on kudus, elands and sable antelopes, and in Uganda a group was found to be sleeping on a giraffe; in Kenya, birds were seen on elands and giraffes at night. There is a report from Zambia of Red-billed Oxpeckers on buffaloes at night. How widespread this behaviour is remains unclear, and it is not known which local conditions may determine the birds' choice of sleeping place.

Molecular techniques were employed in order to determine the sex of Red-billed Oxpeckers in Zimbabwe. The results revealed that the sex ratio among regular group-members was balanced, but that the composition of non-breeding social groups was quite fluid over time. Although the overall sex ratio was 52 males to 108 females, this appeared to be an artefact of the restricted sampling area and the apparent greater mobility of females in all age-classes.

Voice

Oxpeckers hardly rate a mention as songsters, and the vocalizations that have attracted most attention are the alarm calls given while the oxpeckers are perched on their mammalian hosts, and the flight calls emitted by the birds when startled or on their way to or from roost-sites. These are the diagnostic calls for human observers in the field. W. Neweklowsky, however, described two song types for the Red-billed Oxpecker in the Zurich Zoo, in Switzerland. One consisted of a string of soft calls, interspersed with trills and whistles, which were uttered by both male and female of a pair when they were temporarily separated; and the second type was a series of drawn-out whistling notes used in courtship, and seemingly given by the male alone. The full repertoire of oxpecker vocalizations is most likely to be uncovered through monitoring of individuals in captivity, where a close approach is possible, and both birds and host animals are habituated to the presence of humans.

Currently, more attention is being paid to the songs produced by female birds, and it is evident that, with many passerine species, the females do sing, often in the same contexts of territorial defence or courtship as those which elicit song from the males. Future studies of oxpecker vocalizations should, therefore, focus on individually marked birds of known sex.

Food and Feeding

The main food item of the Buphagidae is ticks, with a clear preference apparent for particular species and also for certain stages in the ticks' life-cycle. The Red-billed Oxpecker, especially, feeds primarily on the immature stages of ticks. Lice (Anoplura), fly larvae (Diptera) and leeches (Hirudinea) are also removed from the host's body surface, while flying insects such as dipterans, particularly horseflies (Tabanidae) and blackflies (Simuliidae), are caught in the air. As engorged ticks are in essence small bags of blood, the oxpeckers will also feed directly on blood from wounds, and sometimes on other body fluids such as mucus from the nose or eyes, and even on ear wax, which would seem to have little nutritive value. There seem not to be any major differences in food preferences between the two species, except that, on the basis of comparative studies of a small number of captive individuals, Yellow-billed Oxpeckers may catch more biting insects and take larger ticks, such as engorged females of *Amblyomma hebraeum*, than do Red-billed Oxpeckers.

Oxpeckers remove ectoparasites from their mammalian hosts by two different techniques. One of these involves simple pecking and plucking with the tip of the bill, whereas in the other method, known as "scissoring", the bill is laid sideways against

The main food of both oxpecker species is ticks. There are no major differences in preferred prey between the two species, though on the basis of studies of captive birds, ***Yellow-billed Oxpeckers*** *may take more biting insects and larger ticks, such as engorged females, while Red-billed Oxpeckers* (Buphagus erythrorhynchus) *feed primarily on the immature stages of ticks. Oxpeckers use two techniques to detach ticks from their hosts. The first involves pecking and plucking with the tip of the bill after prey has been located visually. In the second, known as scissoring, the bill is laid alongside the host's skin, and opened and closed; prey is detected by touch. Scissoring is used most often on long-haired hosts such as greater kudu* (Tragelaphus strepsiceros).

[*Buphagus africanus africanus*, Tanzania. Photo: Eyal Bartov]

*One **Red-billed Oxpecker** was found to have 1665 ticks in its stomach. In captivity, oxpeckers have been recorded eating up to 12,000 tick larvae, or 100 adult ticks per day. Although ticks are the main food type, oxpeckers will also eat leeches, lice, biting flies such as horseflies, and alate termites. They stalk flying insects when these settle on the host, and will also hawk them in the air. Other food includes blood, and mucus obtained from the eyes and nostrils of host mammals. In natural habitats, Red-billed Oxpeckers are found chiefly on giraffes, African buffaloes, both African species of rhinoceros, zebras and several species of antelope; other hosts include hippopotamuses, as here, and warthogs.*

[*Buphagus erythrorhynchus*, Serengeti National Park, Tanzania. Photo: Ketil Knudsen]

the skin and is then opened and closed, as with a pair of scissors. The former approach depends on visual location of the prey, while in the latter technique the prey is detected by touch. The feeding style utilized is correlated with the hair structure of the host, with scissoring not employed on nearly hairless animals, such as rhinoceroses or hippopotamuses, except at wounds or when collecting mucus at the nasal openings. The highest frequency of scissoring is observed when the buphagid is on the longest-haired hosts, such as the kudu and the roan and sable antelopes. The head and ear regions are in many cases the areas where the birds spend the majority of their foraging time, and regular hosts are often most accommodating in allowing what appears to the human observer to be an uncomfortable and invasive process. Studies of the impala's interactions with oxpeckers indicate that the antelope grooms less often when visited by the birds, suggesting that it does benefit from the association. In this case, the oxpeckers clearly focus their attention on areas which the impalas are not able to reach effectively by themselves, and where the highest concentrations of ticks are likely to be found.

Two of the common tick prey species, *Amblyomma hebraeum* and *Boophilus decoloratus*, have also been recorded as ectoparasites of both adult and nestling Red-billed Oxpeckers. Since these ticks were found much more frequently on the nestlings, it is possible that they represent live food which had escaped after having been brought to the nest. The other ectoparasites noted, two mites (Acarina) and a feather louse (Mallophaga), are specific to the birds in question and would not have been acquired from their mammalian hosts.

As already noted, oxpeckers often feed at wounds. This behaviour, when directed at the black rhinoceros, is commonly associated with the skin lesions infested with filariid parasites, which are found in this species but not in the white rhinoceros. The possible role of the oxpeckers in delaying the healing of such wounds or in the transmission of the parasites has yet to be clarified, but a research project is currently in progress. Hippopotamuses frequently have wounds resulting from intraspecific fighting, and these are favoured feeding sites for buphagids. Several observers have reported that the birds, as well as taking blood, will remove fragments of tissue from the wounds. There are also observations of oxpeckers feeding on carrion, including the dressed carcases of animals. Oxpeckers held in captivity are routinely maintained on a diet in which the main component is raw minced meat. Despite the implication that oxpeckers may actively feed on the flesh of their hosts, this may be exceptional under natural conditions. Observations on captive rhinoceroses suggested that abrasions healed despite the attentions of the birds. A tame oxpecker fed eagerly on blood from a cut in a human finger, nibbling at the area in order to increase blood flow, but apparently not causing any further damage.

During the translocation of Red-billed Oxpeckers in South Africa, the captured birds were initially held in bomas (livestock enclosures), with donkeys as hosts. This led to problems when the birds opened wounds on the donkeys, such that the latter had to be changed on a regular rotational basis. A simple solution proved to be that of feeding the oxpeckers directly with blood, which was collected from a culled animal and treated with an anticoagulant, along with lean minced meat to which vitamin and mineral supplements had been added. Buphagids on this diet often gained weight during the quarantine period before being released at a new locality, and it was found to be unnecessary to enclose a mammalian "host" with them.

Breeding

At least in the Kruger National Park, in South Africa, the breeding season is closely linked to rainfall, which influences both the grazing activity of the ungulates and the prevalence of ticks. Courtship and copulation take place on the host animal, further illustrating the closeness of the association of these birds with large mammals. In observations of captive birds, the selection of the nest-site appeared to be determined by the male.

The two species of oxpecker normally nest in tree holes, although they have been reported as using other sites, including holes in walls, and J. Vincent even found a nest at the base of a cleft in a large boulder. The cavity is lined with dry grass, and often with the addition of hair plucked from the host mammals; in farming areas this can include wool from sheep (*Ovis*), which the birds seemed to visit for this purpose only. Dung and rootlets may also be added to the interior.

Both members of the family lay clutches of two or three eggs, the Red-billed Oxpecker sometimes laying up to five. Its eggs have a white to creamy, or occasionally very pale blue or pale pink, ground colour heavily speckled with reddish-brown and lilac-grey, or sometimes with pink and maroon speckles on grey and lavender blotches; they measure 22·5–26·5 × 15·8–18·6 mm. Yellow-billed Oxpeckers' eggs are similar, but the speckling is sometimes less heavy or even lacking altogether, and a small sample had dimensions of 23·4–26·6 × 16·6–18 mm. For both species, the incubation period is approximately 13 days. The nestling period of the Red-billed Oxpecker is 27–30 days, whereas that of its less well-known congener appears to be about 25 days.

In captivity, male and female Red-billed Oxpeckers shared incubation duties, and it is likely that this applies to both species under natural conditions. Similarly, the feeding of the young is a joint venture. As with most passerine birds, brood patches develop only on the females.

Co-operative breeding is a regular feature of the social organization of oxpeckers, most helpers apparently being older siblings of the nestlings. In one captive group, other, unrelated adults also assisted in the feeding of the young. Helpers sometimes contribute nesting material during the nest-building stage, but their primary role is that of feeding the young, both nestlings and fledglings.

*Cattle and donkeys are now the primary host species of the **Yellow-billed Oxpecker** in many parts of West Africa and indeed elsewhere. Oxpeckers have been condemned as pests for inflicting injuries on livestock, preventing wounds healing, and even causing the deaths of already-weakened donkeys. On the other hand, traditional cattle herders, especially in areas with tick-borne diseases, often regard oxpeckers favourably, and may have prohibitions against harming them.*

Movements

The principal hosts of the oxpeckers do not undertake long-distance migrations, and the birds are not, therefore, obliged to follow migratory herds of game. Red-billed Oxpeckers do make regular flights each night to roost-sites in reedbeds or trees, but colour-marked individuals which were tracked visually in the Kruger National Park, in South Africa, moved less than 10 km from the capture site, and two individuals had circular home ranges calculated at about 27 km² over a nine-month period. This is likely to be typical in areas with dense game populations and permanent water supplies, but where the game undertake significant seasonal movements one could expect that the oxpeckers would follow. There is one record from Zambia of a Red-billed Oxpecker found 64 km from the ringing site after 16 months, and some

*Oxpeckers have been observed eating carrion, and these **Yellow-billed Oxpeckers** may be feeding on the flesh and blood of this dead hippopotamus* (Hippopotamus amphibius). *The wounds sustained by hippos during their frequent bouts of intraspecific fighting are favourite feeding sites for oxpeckers. Oxpeckers wound-opening and pecking for ticks, especially around sensitive parts like the ears, may be an uncomfortable experience for the host. Some species, including elephants* (Loxodonta), *reject the attentions of oxpeckers, and even individuals of regular host species may attempt to dislodge them.*

[*Buphagus africanus africanus*,
Chobe National Park, Namibia.

*These **Yellow-billed Oxpeckers** have left their host mammals temporarily, in order to drink at this water-hole. Oxpeckers commonly remain aboard when the mammal goes to drink, sometimes running down its leg and taking a few sips of the water without actually detaching themselves from their host. Oxpeckers have been observed leaving their hosts in order to dust-bathe, or to bathe in water. After bathing, they return to perch on the host mammal while they preen their plumage. In Senegal, there are reports that Yellow-billed Oxpeckers will drink fresh cow's milk from containers when these are unattended by the herdsmen.*

[*Buphagus africanus africanus*, Botswana. Photo: Konrad Wothe]

individuals appeared to have moved up to 50 km from the point of release within a year of their reintroduction to reserves in Zimbabwe. Since Yellow-billed Oxpeckers may sleep while perched on the host animals (see General Habits), they could be passively carried by herds of buffaloes, which will occasionally travel up to 8 km in a day.

Despite these indications that oxpeckers are largely sedentary, there are some ringing records which suggest long-distance dispersal or vagrancy. A translocated Red-billed Oxpecker in South Africa returned to the site where it had been captured, 170 km away, and another was found 87 km from the release site. Still in South Africa, prior to the reintroduction of Red-billed Oxpeckers in the Eastern Cape, a single individual was reported from Cape Recife Nature Reserve, near Port Elizabeth, in 1960, and two were sighted on cattle near Kenton-on-sea in 1989. No escapes from captivity had been reported, and the nearest wild populations at that time were more than 1000 km away. There have been no studies of the dispersal of buphagids, nor of any interchange between different groups, but among co-operative breeders such as the oxpeckers the young birds generally leave the natal group in order to attain breeding status. The apparent female-biased sex ratio found in Red-billed Oxpecker groups in a study in Zimbabwe (see General Habits) strongly suggests that females are the dispersing sex, and that, when a breeding female is lost from a group, she is replaced by one of the "floaters" which associate temporarily with different social units. In this study, lone individuals which were resighted after having been ringed, and having had their sex determined, were more likely to be female than to be male.

Relationship with Man

For our hunting forebears, oxpeckers would have been simply a nuisance, since they must often have alerted grazing animals to the approach of human hunters, especially before man had developed weapons which could kill at an appreciable distance. Later, hunters with rifles still found that the birds regularly alerted the quarry to the approach of a human. The nineteenth-century natural-history collector J. A. Wahlberg noted in his journals two occasions on which rhinos escaped his sights after oxpeckers gave the alarm, while on two other rhino hunts the call of an oxpecker first alerted him to the probable presence of the mammals. Wahlberg's contemporary and sometime travelling companion A. Delegorgue wrote of oxpeckers warning buffaloes and elands, as well as rhinoceroses, and commented that, as a hunter, he had cursed the oxpeckers more than he had any other birds. A. R. Maclatchy, a twentieth-century hunter of big game in Gabon, credited the oxpeckers with bringing to his attention the position of a wounded buffalo before the concealed animal charged him, and he considered them a help, rather than a hindrance. He noted also, incidentally, that these birds would return to a wounded buffalo, or even to a freshly killed one.

Conflicting views were evident with regard to the nature of the relationship between oxpeckers and domestic livestock. At the start of the twentieth century, T. Ayres, a transport rider in South Africa, stated that the birds dug large holes in the backs of transport oxen and fully merited their name of "buphaga", which means "ox-eater". Later, A. Vincent noted that, in his experience, oxpeckers within a herd of cattle were seen most often on the bulls, which were probably dipped less often and therefore carried a heavier tick burden. W. L. Sclater and R. E. Moreau wrote that, in Tanzania, oxpeckers were "credited with performing services of the utmost value in cleaning cattle of ticks, and they have been heartily damned for making, and keeping open, wounds". These authors commented that local people had a generally favourable opinion of the birds, whereas European stock-owners considered them a pest. Moreau examined the stomach contents of 58 Red-billed Oxpeckers from Tanzania, and found 2291 ticks in 55 of the birds; one stomach was empty, and two others contained only Diptera. He concluded that the birds were probably beneficial to healthy cattle exposed to ticks, and suggested that stock in poor physical condition were the most likely to suffer damage. V. D. van Someren came to a similar conclusion on the basis of a questionnaire distributed to European farmers in Kenya after the dipping of cattle had become a regular practice. R. E. Cheesman and Sclater described the Red-billed Oxpecker in Ethiopia as "A bird of evil habits, a mule with a saddle gall has little chance of healing, as these birds keep the wound open daily by pecking the live flesh and drinking the blood, and will pick holes for themselves in the skin of a weak or sick donkey." F. J. Jackson, writing of Red-billed Oxpeckers in Uganda, balanced

their positive services to cattle and big game against the damage caused to pack-donkeys and mules "in the old caravan days", and claimed that many donkeys died through the aggravation of sores by the oxpeckers. Once again, the damage was associated with existing injuries and poor condition of the animals. Some 40 years later, however, Y. A. Mengesha stated that oxpeckers in Ethiopia visited animals with sores more often than they did those with ticks, and he observed the birds as they opened wounds on a cow which had no existing skin lesions. According to his informants, many cattle-owners in the region considered the birds to be pests, and took special measures to keep them off the stock. Some traditional cattle-herders still regard the buphagids more favourably in a region with many tick-borne diseases which affected domestic stock prior to the advent of veterinary services. Even in the twenty-first century, in the Mbulu highlands of Tanzania, there was a social prohibition against the harming of oxpeckers, since these birds' important role in reducing the numbers of ticks was familiar to the community.

Studies undertaken by P. Weeks in Zimbabwe suggested that the relationship between Red-billed Oxpeckers and cattle in this region was not beneficial to the cattle, since "wound-feeding" by the oxpeckers was rife, and there was no detectable increase in tick loads on cattle from which the birds had been experimentally excluded. He noted also, however, that cattle are not the hosts with which the birds have co-evolved, and that their relationship with wild game may represent a genuine symbiosis. Observations of captive oxpeckers and black rhinoceroses at Zurich Zoo, in Switzerland, demonstrated that the birds did open new wounds on their hosts, and that the rhinos were intolerant of the birds feeding at wounds and regularly attempted to dislodge them. This was an unnatural situation, especially since the captive rhinos were tick-free, but it suggests that field studies of oxpeckers should focus on the frequency of feeding at wounds, and monitor the frequency with which new wounds are created on game animals.

Although Reichenow quoted South African observers who reported that oxpeckers on cattle flew up when people approached, and were apparently disconcerted at the animals' failure to react to the birds' alarm calls, both Jackson and Archer noted in eastern Africa, some 30–40 years later, how different the oxpeckers' behaviour was when the birds were exploiting domestic stock. In the latter situation, they always moved swiftly to the other side of the animal, away from the human observer, but did not fly up or give alarm calls. Yet within a few kilometres of the cattle herds, oxpeckers on wild game immediately gave alarm calls when people approached. Do oxpeckers foraging on cattle learn to imitate the mammals' indifference to the presence of herdsmen and, as a consequence, stop responding? Do these birds still alternate between foraging on wild animals and exploiting domestic animals, or are there "specialist" populations which favour one host category above the other? At this stage, we have no clear answers to these questions.

Status and Conservation

In both southern and eastern Africa, the reduction in size of the herds of wild game, and in particular the displacement of the rhinoceros and buffalo, have removed favoured oxpecker hosts. Game control, a euphemism for large-scale attempts to eradicate wild animals from areas selected for stock-farming, was frequently linked to campaigns to eliminate the tsetse fly (*Glossina*), the insect vector of trypanosome parasites which killed the imported animals but left the indigenous wildlife unaffected. Although domestic cattle are acceptable replacement hosts for the oxpeckers, rinderpest epidemics at the end of the nineteenth century seriously reduced the populations of both cattle and buffaloes. Soon after this, a regular animal-dipping regime was introduced in many farming areas in an effort to reduce stock losses from tick-borne diseases. Not only were tick populations greatly reduced by dipping, but the early arsenical dips were highly toxic to the birds, and this led to the rapid disappearance of oxpeckers from areas under the influence of European colonists.

Thus, whereas C. Belcher had reported pre-1920 observations indicating that Yellow-billed Oxpeckers were common on cattle at Chiromo, in Malawi, this buphagid had virtually disappeared from the country when C. W. Benson reviewed the Malawi avifauna, in 1977, and according to the most recent atlas data it is now confined to two game reserves. The Red-billed Oxpecker, too, is virtually restricted to protected areas with wild ungulates, and in the past 50 years there have been only two reports of this species on cattle in Malawi. Commercial farmers in the Makonde district of Zimbabwe noted the return of Red-billed Oxpeckers

Both oxpecker species nest in tree holes, although they have been reported using other sites such as clefts in rocks and walls, and even holes in buildings. The ***Yellow-billed Oxpecker*** *chooses a site two to seven metres above ground, and lines the cavity with hair plucked from host animals, dry grass, and sometimes feathers. In at least part of the range, the oxpecker breeding season is linked to rainfall, which influences the grazing activities of host mammals, and the abundance of ticks. Courtship and copulation take place on the back of the host mammal. Both species generally lay two or three eggs.*

to the area some 50 years after they had last been reported in the district. This was apparently associated with the cessation of tsetse-fly control programmes, which had involved both elimination of wild game and pesticide-spraying, followed by the re-establishment of game on many properties.

When C. J. Stutterheim reviewed the historical distribution of oxpeckers in South Africa, he concluded that the Red-billed Oxpecker had disappeared from the southern part of its range in the Eastern Cape province coincidentally with the widespread introduction of cattle-dipping early in the twentieth century, while it survived in the north-east of the country primarily in game reserves or in tribal lands, where cattle were not dipped regularly. The Yellow-billed Oxpecker seems always to have been less common in the region, and was restricted to the north-eastern sector. It was considered extinct in South Africa by 1965, and may have disappeared as a breeding species much earlier than that. In 1979, however, Yellow-billed Oxpeckers reappeared in the Kruger National Park, in the north-east part of South Africa, where there had been no confirmed records of the species since 1896, and juveniles were sighted in 1984. This oxpecker had evidently colonized the area from north of the Limpopo River, which forms the northern boundary of the park, since there were still Yellow-billed Oxpecker populations in southern Zimbabwe. It was suggested that the breakdown in the regular dipping of cattle and in control over the movements of both cattle and game during the later phases of the war in Zimbabwe facilitated the dispersal of these birds through this region. In 2000, the number of Red-billed Oxpeckers in the Kruger National Park was estimated at more than 32,000 individuals, whereas the estimated population of Yellow-billed Oxpeckers in the park was about 500. The latter species clearly remains an uncommon bird there.

The first attempts at reintroducing oxpeckers in areas from which they had been extirpated were made in Zimbabwe. In 1962, after heavy tick loads had been noted on newly established wild game in McIlwaine National Park, oxpeckers of both species were captured in Hwange National Park (at that time known as Wankie National Park), and two days later released in McIlwaine. Observers recorded that Burchell's zebras stampeded on the approach of the oxpeckers, and blue wildebeest also refused to allow the birds to settle on them; an eland cow even rolled in attempting to dislodge the oxpeckers. In contrast, a giraffe immediately accepted the birds. Nonetheless, the buphagids failed to establish themselves in this park. Then, in 1975, totals of 47 Yellow-billed and twelve Red-billed Oxpeckers, again having been captured in Hwange, were released in the Matobo National Park (then known as the Rhodes Matopos National Park). This exercise was successful in the case of the Yellow-billed Oxpeckers, but the number of Red-billed Oxpeckers was presumably too small to facilitate the establishing of a viable population. Subsequently, however, Red-billed Oxpeckers were reintroduced successfully at other Zimbabwe localities.

Both species of oxpecker have now been reintroduced successfully in South Africa. In 1986, 43 Yellow-billed Oxpeckers from Namibia were transported to the Umfolozi Game Reserve, in KwaZulu-Natal, where breeding in the wild was reported within two years. Red-billed Oxpeckers returned to the Eastern Cape in 1990, with releases made in the Addo National Park, in the Great Fish Reserve, and on a private game farm. Sightings of dark-billed juveniles confirmed that the oxpeckers were breeding successfully, and individuals of both species were also breeding in captivity in holding aviaries. Subsequently, more oxpeckers have been released at these locations, at other protected areas and on farms in this province, and on cattle ranches and reserves elsewhere in the country. Farmers have been encouraged to view oxpeckers as allies in the struggle to control tick burdens on cattle, in conjunction with new chemical agents which are "bird-friendly" and can be used with reduced frequency once the oxpeckers are well established. If this programme is a success, it will offer a much wider distributional range to oxpeckers than merely large game reserves with adequate populations of wild ungulates. Nevertheless, it is clear that the contribution of oxpeckers should not be overemphasized, and they are best seen as one element of an integrated pest-management programme for tick populations.

*The nestlings of **Red-billed Oxpecker** are fed by both parents, and also by helpers, which are usually older siblings, though unrelated adults assisted in one captive group. Up to seven birds have been recorded feeding a brood. Following incubation, lasting about 13 days, the nestling period is up to 30 days for Red-billed Oxpecker. Fledglings feed themselves by 21 days, and after 40 days, begging is aggressively rejected by the adults, although the young may be fed by helpers in the months following fledging. Predation is suspected to be the main source of nestling mortality in the Red-billed Oxpecker. In one study, 72 eggs produced 29 flying young.*

[*Buphagus erythrorhynchus*, Nylsvlei Nature Reserve, South Africa. Photo: Hugh Chittenden]

Since oxpeckers are dependent on hollow trees for nesting, but cannot make their own nest-holes, both veld fires and firewood-collecting reduce their nesting opportunities. This may force them to use less suitable sites, those more accessible to predators, and this often results in lower breeding success. Both drought and fire also have a clear impact on tick populations, and these factors were considered responsible for a decline in the population of Yellow-billed Oxpeckers in the Caprivi region of Namibia. Fire is commonly employed as a management tool in protected areas, and it is increasingly being recognized that the timing and consequent intensity of fires are important in determining the maintenance of dead trees, which provide a habitat for many birds, mammals and other organisms.

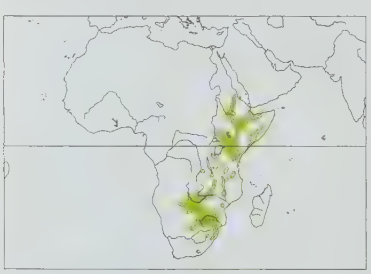
PLATE 39



Genus *BUPHAGUS* Brisson, 1760

1. Red-billed Oxpecker

Buphagus erythrorhynchus

French: Piqueboeuf à bec rouge **Spanish**: Picabueyes Piquirrojo
German: Rotschnabel-Madenhacker

Taxonomy. *Tanagra erythrorhyncha* Stanley, 1814, Ethiopia.
Hybrids with *B. africanus* recorded in Zimbabwe. Birds from R Palala, in N South Africa (E Limpopo Province), described as race *caffer*, and birds from Panda, in S Mozambique (Inhambane District), as race *scotinus*, but both considered inseparable from birds in rest of species' range; other proposed races include *invictus* (Somalia, NE Kenya), *angolensis* (SE Angola) and *bestiarum* (S Zimbabwe). Monotypic.
Distribution. Eritrea, Ethiopia, Djibouti, extreme SE Sudan and N, W & S Somalia S, patchily, to SE DRCongo, Zambia, Malawi, extreme SE Angola, NE Namibia (Caprivi region), N & E Botswana, Zimbabwe, N & E South Africa, Swaziland and S Mozambique.

Descriptive notes. 20 cm; 42–59 g. Somewhat variable, with dark olive-brown head to throat and tail, mantle often comparatively paler, most of upperwing darker and more olive-grey; chest to undertail-coverts lighter brown, thighs dark brown; iris yellow to red, bare skin around eye yellow; bill laterally flattened, slightly bulbous towards centre, bright red; legs grey-brown to black. Sexes alike. Juvenile is like adult in plumage; bill initially yellow (at fledging) but changing to dark brown within 2 months, then to red at c. 7 months, eyes dark brown, becoming partly yellow at 4 months and as adult by 6–7 months. Voice. Male song of soft calls interspersed with trills and whistles; in courtship, drawn-out whistling notes. Female has soft song like that of male, may be used for maintaining vocal contact. Sharp hissing "ksss" in alarm; flight call "tsik tsik". Nestlings hiss in alarm; begging call of young "tji tji". Wild ungulates such as rhinoceroses (*Ceratotherium*, *Diceros*) respond to alarm calls of adults.
Habitat. Savanna woodland and farmland, up to 3000 m; absent from forested regions and from arid, treeless areas. Trees required for roosting and breeding. Occurrence dependent on presence of wild ungulates or domestic stock, on which the birds spend almost all of their time.
Food and Feeding. Diet primarily ectoparasites of large mammals, mainly ticks (Ixodoidea), also mites (Mesostigmata), lice (Anoplura), leeches (Hirudinea) and biting flies (Diptera); termite alates (Isoptera) also taken; in addition, feeds to varying extent on blood and mucus from host animal. Ticks mostly of genera *Amblyomma*, *Boophilus*, *Hyalomma*, *Ixodes* and *Rhipicephalus*; flies include particularly those of family Tabanidae, also some of Muscidae. One individual had 1665 ticks in stomach; in captivity ate up to 12,000 tick larvae or 100 adult ticks per day. Cattle are primary hosts in settled areas, where utilizes also donkeys, mules, camels, pigs, even sheep and goats. In game reserves and natural habitats found chiefly on giraffe (*Giraffa camelopardalis*), African buffalo (*Syncerus caffer*), black rhinoceros (*Diceros bicornis*), white rhinoceros (*Ceratotherium simum*), eland (*Taurotragus oryx*), greater kudu (*Tragelaphus strepsiceros*), sable antelope (*Hippotragus niger*), Burchell's zebra (*Equus burchellii*), and impala (*Aepyceros melampus*); also on roan antelope (*Hippotragus equinus*), hippopotamus (*Hippopotamus amphibius*), warthog (*Phacochoerus aethiopicus*), blue wildebeest (*Connochaetes taurinus*), nyala (*Tragelaphus angasi*), lesser kudu (*Tragelaphus imberbis*), oryx (*Oryx gazella*), and large gazelles such as Sömmering's gazelle (*Gazella soemmeringii*). Some mammals, e.g. African elephants (*Loxodonta africana*), common waterbuck (*Kobus ellipsyprimnus*) and bushbuck (*Tragelaphus scriptus*), and even some individuals of regular host species, may reject attentions of oxpeckers by dislodging them, using tail, trunk and horns, and on occasion resorting to rolling. Stalks insects landing on host; also hawks flying insects. Attached parasites are grabbed in bill tip and plucked off skin if visible; ticks hidden in fur are collected by scissoring, in which bill is laid against surface and opened and closed rapidly while being pushed through hair. Pecking, in woodpecker (Picidae) style, with bill closed or slightly open, used both to remove parasites and to open wounds on host. Scissoring employed also to collect fluid at mouth or nasal openings of host, or blood from wounds. Removes scabs and keeps injuries open in order to feed on blood, although areas kept free of maggots and infected tissue; will also create wounds, particularly on domestic animals in poor condition. Diet and feeding methods essentially similar to those of *B. africanus*. Compared with latter, perhaps take smaller ticks, and may spend less time in feeding at wounds. Forages in

small groups, and up to 15–20 individuals seen on a single giraffe. Sometimes found alongside its congener on same host mammal.

Breeding. Breeds following rainfall, Jan–Mar in Eritrea, Ethiopia and Somalia (recorded also Apr, Jul and Aug in Ethiopia); recorded in all months in Kenya and Tanzania, Dec–Feb in Zambia, Oct in Malawi, Oct–Dec in Botswana, Nov–Dec in Zimbabwe, and Oct–Mar in South Africa; up to three broods per season in Kruger National Park, in South Africa. Mating system monogamous; co-operative breeder, pair assisted by group of helpers (adults and subadults), which feed nestlings and fledglings. Courtship, involving wing displays and courtship feeding, and copulation take place on mammal host. Nest composed of hair plucked from host mammals, dried dung, grass and rootlets, placed in natural tree hole 1–15 m above ground, sometimes in cleft in stone or gap in stone wall, site may be used in successive years; only nest-site defended, and no extended territory. Clutch 2–5 eggs, mean 3 (Kruger National Park); eggs white to creamy, less often pale blue or pale pink, usually heavily speckled with reddish-brown and lilac-grey, but sometimes pink and maroon speckles on grey and lavender blotches; incubation by both sexes, period 12–13 days; nestlings fed by both parents and by helpers, up to seven birds feeding brood at one nest, nestling period 27–30 days; fledglings feed themselves by 21 days, and by 40 days begging approach usually aggressively rejected by adults, but young occasionally fed by helpers for up to 90 days after fledging. Few data on breeding success: 49% of eggs laid hatched, and 72 eggs produced total of 29 flying young; predation suspected as main cause of nestling mortality.

Movements. Resident, with only local movements of up to 50 km recorded. Daily flights from roost-sites to relocate host mammals, and homing ability over more than 100 km demonstrated by a translocated bird. Dispersal from natal group likely to be female-biased, and dispersing individuals or vagrants may occasionally move up to 1000 km.

Status and Conservation. Not globally threatened. Widespread in E & SE Africa, and common in game reserves; in 2000, estimates of more than 32,000 individuals in Kruger National Park (South Africa) and more than 3000 in adjacent Mozambique. Current distribution patchy compared with historical records. Successfully reintroduced in parts of former range, and in some regions encouraged in ranching areas as a biological control agent for ticks on domestic stock, in conjunction with chemical control which is not toxic to the birds. Previously, numbers and range greatly reduced as a result of destruction of wild game, and use of toxic chemicals for dipping domestic stock. Beneficial in removing ectoparasites from large mammals, but this must be balanced against direct harm caused by feeding on blood of domestic livestock. Occurs in numerous protected areas, e.g. Tarangire National Park and Mikumi National Park, in Tanzania, Liwonde National Park, in Malawi, and Mahango Game Reserve, in Namibia.

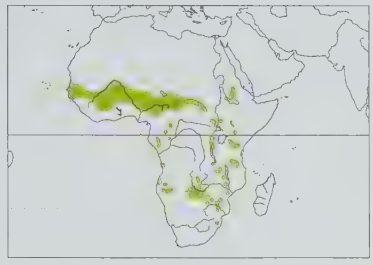
2. Yellow-billed Oxpecker

Buphagus africanus

French: Piqueboeuf à bec jaune **Spanish**: Picabueyes Piquigualdo
German: Gelbschnabel-Madenhacker
Other common names: Tickbird

Taxonomy. *Buphaga africana* Linnaeus, 1766, Senegal.



Hybrids with *B. erythrorhynchus* recorded in Zimbabwe. Proposed races *megarhynchus* (described from L Kivu, in E DRCongo) and somewhat larger *haematophagus* (from Andara, on R Okavango, in NE Namibia) synonymized with nominate. Two subspecies recognized.

Subspecies and Distribution.

B. a. africanus Linnaeus, 1766 – SW Mauritania and Senegal E to W, S & E Sudan, NW Ethiopia and W Eritrea, also locally SW Angola (S from Huíla) and N & NE Namibia and, in E, very locally from Uganda and Kenya S to Zambia, Malawi, N Botswana, Zimbabwe, C Mozambique and NE South Africa.

B. a. langi Chapin, 1921 – Congo Basin in Gabon, PRCongo, W DRCongo, and W Angola (S to Benguela).

Descriptive notes. 20 cm; 57–71 g. Somewhat variable. Nominate race has dark brown to olive-grey head to throat, mantle, back, upperwing and tail, contrasting light fawn rump and uppertail-coverts, sometimes with greyish wash; chest to undertail-coverts light brown; iris red,bounded by narrow yellow inner and outer rings; bill laterally flattened, with broad base of lower mandible and bulbous near tip, yellow, distal portion red; legs dark brown to blackish. Sexes alike. Juvenile has plumage like adult, initially has yellow bill and narrow yellow ring around brown eye; within

weeks, both bill and eyering become dark brown, and adult coloration attained within first year. Race *langi* is smaller than nominate, also darker, with greyish rump. Voice. No song described. Buzzing flight call, and high "peep peep" from circling and displaying birds; hissing "kriss kriss" in alarm. In addition to begging calls, young give hollow "chok" calls, and intense snake-like "tchisss" sound in alarm. Wild ungulate hosts, particularly rhinoceroses (*Ceratotherium*, *Diceros*), respond to alarm calls of adult birds.

Habitat. Open savanna, but occurrence dependent on presence of suitable mammalian hosts. Spends virtually all of its time perched on host mammal, and will even sleep there; roosting in trees reported in some areas.

Food and Feeding. Diet primarily ectoparasites of large mammals, and includes ticks (Ixodoidea), lice (Anoplura), fleas (Siphonaptera) and biting flies (Diptera); also blood and other body fluids taken from host. Among recorded food items are ticks of genera *Boophilus* and *Rhipicephalus*, the louse *Damalina bovis*, and the flea *Haematopius suis*. In Senegal, drinks fresh cow's milk from containers when unattended by herdsmen; report from Gambia of nestlings being fed with meat, apparently taken from tethered cattle. Captive individuals ate up to 13,000 tick nymphs or 100 engorged adult ticks per day. Cattle and donkeys now the primary host species in many parts of W Africa, and widely used elsewhere. Of wild ungulates, African buffalo (*Syncerus caffer*) seems to be first choice, with black rhinoceros (*Diceros bicornis*), white rhinoceros (*Ceratotherium simum*), giraffe (*Giraffa camelopardalis*), eland (*Taurotragus oryx*), greater kudu (*Tragelaphus strepsiceros*), zebra (*Equus*), roan antelope (*Hippotragus equinus*), sable antelope (*Hippotragus niger*), hippopotamus (*Hippopotamus amphibius*) and impala (*Aepyceros melampus*) also used regularly; more occasional hosts include warthog (*Phacochoerus aethiopicus*), blue wildebeest (*Connochaetes taurinus*), hartebeest (*Alcelaphus lichtensteinii*) and tsessebe (*Damaliscus lunatus*). Catches flying insects, either on the host or in air; pecks and plucks at wounds and parasites. Collects fluids or ticks concealed in hair of host by using scissoring technique, whereby bill is laid against surface and opened and closed rapidly while being pushed through the mammal's hair. Both food selection and feeding methods essentially similar to those of *B. erythrorhynchus*. Compared with latter, may take larger ticks, particularly engorged females, and spend more time in feeding at wounds. Forages in small groups, and up to 20 individuals seen on a single buffalo. Sometimes found alongside its congener on same host mammal. Several separate groups of oxpeckers may utilize one herd of mammals.

Breeding. Breeds Jun–Sept in Mauritania and Senegal, Apr–Aug in Nigeria, May–Jun in Sudan, mostly Dec–Jun in E Africa, chiefly May–Aug in highland Kenya, Dec in Zambia, and Sept–Mar in Botswana and Zimbabwe. Mating system monogamous; co-operative breeder, pair assisted by 1–6 helpers (extra adults) in raising young. Courtship may involve aerial displays; defends nest cavity against conspecifics and other competitors, e.g. starlings (Sturnidae) and parrots (Psittacidae). Nest in tree hole, either natural cavity or old woodpecker (Picidae) hole, 1·5–15 m above ground (mean 6 m in Kenya), cavity lined with hair plucked from host animals, dry grass, twigs and sometimes feathers; some reports of nesting in buildings. Clutch 2–3 eggs, white to creamy, less often pale blue or pale pink, sometimes plain, or else speckled and blotched with reddish-brown and grey; incubation period 13 days or longer; chicks fed by both parents and by helpers (3–4 adults seen to feed young at two nests), nestling period c. 25 days. No information on breeding success.

Movements. No direct studies; recolonization of Kruger National Park (in South Africa) from Zimbabwe indicates that regular dispersal must occur.

Status and Conservation. Not globally threatened. Locally common, with extensive but fragmented range; categorized as "vulnerable" at S end of range. More localized than *B. erythrorhynchus*, but reasons for this not apparent. In Kruger National Park, in South Africa, population estimated at 500 individuals in 2000; completely absent from the park until 1979, when natural recolonization from Zimbabwe began. Survival of C Mozambique population dependent on protection of game herds. In S Africa, reintroduced successfully both in protected areas and in farmland where chemical control of ticks uses products non-toxic to birds. Species was reduced in range and numbers by past destruction of game and also by introduction of dipping programmes for domestic livestock in which toxic chemicals utilized, but has made significant recovery. Present in many protected areas, including e.g. Waza National Park, in Cameroon, Murchison Falls National Park, in Uganda, Mikumi National Park, in Tanzania, Mahango Reserve, in Namibia, and Kruger National Park, in South Africa.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family STURNIDAE (STARLINGS)

- Small to medium-sized passerines with slender to heavy bill; plumage coloration often black, or with brilliant iridescent structural colours.
- 15–45 cm.

- Africa, Eurasia, Pacific islands, and north-east Australia; introduced in many parts of world.
- Forest, grassland, scrubland, orchards, plantations, gardens, villages, urban areas.
- 31 genera, 112 species, 215 taxa.
- 8 species threatened; 5 extinct since 1600.

Systematics

The starlings are an Old World group, with notable radiations in Africa and Asia, including the successful colonization of many Pacific Ocean islands. The family name Sturnidae, proposed in 1815 by C. Rafinesque, is derived from the Linnaean generic name for the Common Starling (*Sturnus vulgaris*) of Europe.

One of the earliest taxonomic overviews was presented by G. R. Gray in his list of the genera of birds. His family Sturnidae was divided into seven subfamilies, three of which comprised New World blackbirds (Icteridae); the other four incorporated genera still widely recognized as starlings, including a separate subfamily for the oxpeckers (*Buphagus*). The brilliant plumage of the African glossy starlings made them a feature of early museum collections, and G. Hartlaub provided early reviews of their taxonomy, while also recording the available biological information. In the first version of *A Catalogue of the Birds in the British Museum*, published in 1877, R. B. Sharpe proposed that the starlings be divided into two families, the Sturnidae, including such genera as *Sturnus*, and the Eulabetidae, which incorporated the glossy starlings from both Africa (*Lamprotornis*) and Asia (*Aplonis*). In 1890, however, Sharpe placed the starlings in a single family, Sturnidae, with the two subfamilies Sturninae and Buphaginae, the latter for the two oxpecker species, alongside the woodswallows (Artamidae), the weavers (Ploceidae), incorporating the waxbills (Estrildidae) and indigobirds (Viduidae), and the larks (Alaudidae). Thus, from an early stage, the oxpeckers were viewed as aberrant starlings.

A. Reichenow associated the starlings with the crows (Corvidae), the drongos (Dicruridae), the orioles (Oriolidae) and the birds-of-paradise (Paradisaeidae), noting only that the tenth, outermost primary (in his numbering the first primary) was much shorter than in members of these groups; he divided the starling species into 37 genera, which included the oxpeckers. H. von Boetticher, like Sharpe, proposed a link with the weaver family, but his comparison of bill structure, vocalizations and nesting behaviour relied on shared characters which were primitive, rather than derived. P. R. Lowe examined skull structure and head musculature, and concluded that Sharpe's proposed division of the starlings into two families, Sturnidae and Eulabetidae, was essentially a functional division into arboreal frugivorous species and ground-feeding, mainly insectivorous starlings. Lowe was also interested in the taxonomic position of the picathartes (*Picathartes*) of the western Afrotropics, and on the basis of their cranial anatomy, in particular the distribution and coloration of the bare areas of skin, he suggested that the two picathartes species might form a subfamily (Picathartinae) of the Sturnidae, along with the Sturninae, Eulabetinae and Buphaginae. Today, the picathartes, known also as rockfowl, are considered to represent an ancient family (Picathartidae) of African origin, with no close links to either the crows or the starlings, the groups with which they were "traditionally" associated; they are believed to be, instead, most closely related to the rockjumpers (*Chaetops*), which are confined to South Africa and Lesotho.

The first authoritative classification of the starling family was set out by D. Amadon, and the 27 genera which he had defined for J. L. Peters's *Check-list of Birds of the World*, published in 1962, were used by most subsequent authors, although Amadon did not cite two publications in German, by von Boetticher, which proposed a number of larger genera with a series of subgenera. B. P. Hall and R. E. Moreau, in their 1970 *An Atlas of Speciation in African Passerine Birds*, followed Amadon's arrangement of the African starlings. Hall and Moreau based their species groupings on the visible characters of museum study skins, together with distributional records, relying heavily on the material available in the collections of what was then the British Museum (Natural History), now known as the Natural History Museum. A departure from this "traditional arrangement" was the checklist produced by H. E. Wolters, who recognized a total of 41 starling genera, and retained the oxpeckers within the family, rather than placing them, as Amadon had done, in a separate subfamily. All of these arrangements were founded on earlier anatomical studies of the skeleton and musculature, along with similarities in plumage characters. Study-skin collections in the larger museums could incorporate all living species in the starling family, yet the anatomical descriptions were always based on a much smaller subset of the taxa. Wolters stated that his checklist was based on cladistic principles, using shared derived characters (synapomorphies) as the key features and not relying on mere overall similarity as a guide, but he provided no explicit data on the characters which he had used and how they had been scored.

From a survey of egg-white proteins of passerines, C. G. Sibley noted some differences among the starling genera, and tentatively suggested possible relationships with the bulbuls (Pycnonotidae), the drongos or the woodswallows. On the basis of similarities in the egg-white proteins and of some features of nesting biology, Sibley and J. E. Ahlquist later proposed that the southern African sugarbirds (*Promerops*) might be derived from starlings. This specu-

lation was not, however, supported by subsequent studies of sugarbirds. Within the African starlings, A. J. F. K. Craig and A. Hartley proposed the arrangement of melanin granules within the feathers, the basis of the structural colours, as an additional character by which to define the genera, and this indicated that several of the accepted starling genera, as defined by visible plumage characteristics, were not monophyletic. A preliminary cladistic phylogeny for the African genera based on morphological and biological characters recognized *Creatophora* as being closest to the Asian *Acridotheres* and *Sturnus*, and suggested some reassignments for the species of glossy starling. There was little anatomical support for a link to the crow family: the corvid humerus has a large single fossa, whereas all starlings examined have a double fossa, which does, however, characterize many other passerine families.

Following their studies in which they employed the method of DNA–DNA hybridization, Sibley and Ahlquist concluded that the starlings were the closest relatives of the New World mockingbirds (Mimidae), and they erected a new superfamily, Muscicapoidea, which included the Sturnidae and the Mimidae together with the thrushes (Turdidae) and the Old World flycatchers (Muscicapidae). This novel suggestion was soon tested by other studies using DNA–DNA hybridization, and then by molecular phylogenies in which both mitochondrial DNA and nuclear DNA were analysed. It is now regarded as well supported by all the available data. While relationships at the family level seemed to be resolved, too few species had been sampled to define the genera of starlings, and C. J. Feare and Craig, in their 1998 monograph on the Sturnidae, used only morphological and biological characters to suggest generic assignments.

The most recent molecular studies have further refined the relationships within the family, and provided tentative dates for the separation of the major lineages. D. Zuccon and his co-workers examined DNA from 29 starling species, together with the two Philippine endemics in the genus *Rhabdornis*. Their results placed the oxpeckers, for long treated as aberrant starlings, as basal to the starlings and the mockingbirds, and they suggested that this lineage had diverged from the ancestral sturnoid group more than 22 million years ago, the split between Sturnidae and Mimidae occurring shortly after that. On their tree, three major starling lineages were identified. One of these was an Asian group including the genera *Aplonis*, *Ampeliceps*, *Gracula*, *Mino*, *Sarcops* and *Scissirostrum* with *Rhabdornis* as an early offshoot, which separated more than 17 million years ago, with *Aplonis* as the youngest branch, having separated about 5 million years ago. The second was an African group, separated 13–17 million years ago, which included Sharpe's Starling (*Pholia sharpii*), placed in the genus *Cinnyricinclus* by Zuccon and colleagues, *Poeoptera*, and some *Lamprotornis* and *Spreo* species. The third lineage identified was a Eurasian–African group made up of *Acridotheres*, *Sturnus* and *Creatophora*, which diverged less than 7 million years ago, the Black-bellied Glossy Starling (*Notopholia corrusca*), then placed in *Lamprotornis*, separated about 13 million years ago, *Onychognathus*, the Madagascan Starling (*Hartlaubius auratus*), which was placed in *Saroglossa*, and the Amethyst Starling (*Cinnyricinclus leucogaster*).

I. Lovette and D. Rubenstein sampled the family much more thoroughly, including 91 starling species in their study, which used both mitochondrial and nuclear genes. They retrieved the same broad pattern, with the oxpecker genus, *Buphagus*, basal to the starlings and the mockingbirds; and then, within the starlings, an initial separation of a tropical Asian clade made up of *Aplonis*, *Ampeliceps*, *Enodes*, *Basilornis*, *Gracula*, *Mino*, *Sarcops*, *Scissirostrum* and *Streptocitta*, with *Rhabdornis* as a distant member, and a second group of mainly Palearctic and Afrotropical starlings but with a few species with ranges extending into tropical Asia. Within this second branch, six clades can be recognized: (1) the Afrotropical Amethyst Starling and the Madagascan Starling; (2) all species formerly in the African genus *Spreo* and most members of the African genus *Lamprotornis*; (3) the Copper-tailed Glossy Starling (*Hylopsar cupreocauda*) and Purple-headed Glossy Starling (*Hylopsar purpureiceps*) of West Africa together with the Black-bellied Glossy Starling of eastern African, all three of which were at the time included in *Lamprotornis*; (4) the African forest-dwelling genera *Poeoptera* and *Pholia* along with the monotypic African genera *Grafisia*, *Neocichla* and *Speculipastor*, as well as the Spot-winged Starling (*Saroglossa spiloptera*) of Asia; (5) the genus *Onychognathus*, which ranges from Africa into the Arabian Peninsula; and (6) the Eurasian genera *Acridotheres*, *Leucopsar* and a broadly defined genus *Sturnus*, together with the Afrotropical species the Wattled Starling

*In the **Sulawesi Crested Myna**, as in other members of the Asian genus* Basilornis*, the feathers of forehead, crown and nape form a rigid crest. Only a few sturnids show such prominent crests, and all are Asian. As well as having distinct morphological traits, starlings of the Asian lineage differ behaviourally from their African counterparts. Recent DNA studies indicate that the starlings are the closest relatives of the New World mockingbirds (Mimidae). The oxpeckers (Buphagidae), long treated as aberrant starlings, probably diverged from the ancestral sturnoid group more than 22 million years ago, with Sturnidae and Mimidae splitting shortly afterwards.*

[*Basilornis celebensis*, Tangkoko-Dua Saudara Nature Reserve, N Sulawesi. Photo: Mark Jones/Roving Tortoise Photos]

*The **Golden Myna** of New Guinea is a medium-sized, distinctively patterned sturnid, with a patch of bare dark blue skin around the eye, extending to a point towards the rear. A white patch on the primaries forms a conspicuous wingbar in flight. Pale patches on the wing are found in all three* Mino *species and in a number of other sturnid genera. A pale rump patch, contrasting with the back plumage, is relatively uncommon in this family, being found in the* Mino *species and in eight other sturnids. The significance of such "flash coloration" is uncertain, as many highly social starlings which flock regularly lack any of these signal features.*

[*Mino anais orientalis*, New Guinea. Photo: Tom and Pam Gardner/FLPA]

(*Creatophora cinerea*). The separation of the two species formerly placed together in *Saroglossa* and their association with very different African taxa is a surprise, as are the separation of the Black-bellied Glossy Starling from other members of the genus *Lamprotornis*, and the close link implied between *Poeoptera* and *Pholia*. The Copper-tailed Glossy Starling and Purple-headed Glossy Starling, on the other hand, had already been placed in a separate genus, *Hylopsar*, by Feare and Craig in their 1998 monograph, while *Creatophora* has for a long time been linked with the *Acridotheres* and *Sturnus* group on the basis of its morphology and behaviour. Rubenstein and Lovette later repeated their analysis for the African starlings, including the only missing taxon, Neumann's Starling (*Onychognathus neumanni*). This corroborated the monophyly of the genus *Onychognathus*, but did not modify any of the other relationships suggested above.

The results of these two molecular studies are in broad agreement, although taxon-sampling was still incomplete for the Asian species. Consequently, no new taxonomic arrangement can be recommended for *Basilornis* at this stage, although this genus may not be monophyletic. The Madagascan Starling, formerly thought to be linked to the Asian *Saroglossa spiloptera* on the grounds of morphological similarity, seems to have been separate from the Amethyst Starling for a long time, and it is considered best, therefore, to use the monotypic genus *Hartlaubius* for the Madagascan taxon. The Philippine species in *Rhabdornis* are now treated as a separate family, Rhabdornithidae, and the oxpeckers likewise form the discrete family Buphagidae, immediately preceding the Sturnidae. For the Afrotropical starlings, the present treatment follows that of Lovette and Rubenstein in using the genus *Hylopsar* for the Copper-tailed Glossy and Purple-headed Glossy Starlings, and the genus *Notopholia* for the Black-bellied Glossy Starling, while expanding the genus *Lamprotornis* to include all the species previously placed in *Spreo* (or in *Cosmopsarus*), but provisionally retaining the genus *Pholia*, rather than including its two species in *Poeoptera*. Although all the species in *Pholia* and *Poeoptera* are forest frugivores from the same region of Africa, the differences in sexual dimorphism and juvenile plumages suggest that, while they may be members of the same clade, they should not be treated as congeneric.

It was readily apparent that Amadon's genus *Sturnus* contained species of differing structure, morphology and behaviour, and Feare and Craig, in their earlier handbook on the Sturnidae, proposed the division of the genus into several genera. In particular, they separated what they regarded as "true" *Sturnus*, defined as highly gregarious and largely terrestrial foragers that have a well-developed "open-bill probing" technique for extracting subsurface invertebrates from grassland (see Food and Feeding), from the generally smaller and more arboreal species with a diet including large quantities of nectar, placing the latter in a resurrected genus *Sturnia*. In addition, they moved two species, the Black-winged Myna (*Acridotheres melanopterus*) and the Vinous-breasted Myna (*Acridotheres burmannicus*), from *Sturnus* to *Acridotheres* on the basis of their close behavioural and vocal resemblances to the latter myna genus, and they retained *Leucopsar* and *Gracupica* as separate genera, this interpretation again based largely on the species' behaviour and vocalizations.

Lovette and his team have now produced a molecular phylogeny for this Eurasian radiation, Zuccon's group of workers following closely, and the present classification represents a modification made in the light of their major conclusions. They agree with Feare and Craig's earlier arrangement in placing ten species, including the Black-winged and Vinous-breasted Mynas, in *Acridotheres* and in retaining the monotypic genera *Creatophora*, *Leucopsar* and *Pastor*. The genus *Sturnus*, however, is now restricted to two species, the Common and Spotless Starlings (*Sturnus unicolor*), which emerge as basal to this radiation and which, furthermore, differ very little from each other in genetic terms. This is in agreement with earlier allozyme comparisons of Common and Spotless Starlings, which implied a very low level of genetic differentiation. Following the current expansion of their ranges and local sympatry in the Iberian Peninsula, hybrids between the two species are reported quite regularly in the field. If introgression continues, it is possible that, at some future stage, the Spotless Starling may revert to its original taxonomic status as a subspecies of the Common Starling.

The molecular data support the inclusion of the Asian Pied Starling (*Gracupica contra*) and the Black-collared Starling (*Gracupica nigricollis*) in the genus *Gracupica*, but there is no support for a broad genus *Sturnia*. The White-faced Starling (*Sturnornis albofrontatus*), confined to Sri Lanka, appears to be highly distinctive, and is assigned to a monotypic genus. This species was formerly known as *Sturnus senex*, but was renamed

Starlings range in body mass from about 35 g up to at least 290 g. None is truly tiny, nor are any of the family near the upper end of the size range for passerines, although at 32 cm, the ***Nias Hill Myna****, the largest of the sturnids, reaches the size of the smaller crows. It is notable for its heavy and strongly curved bill. The Nias Hill Myna has a large patch of bare, yellow skin below the eye, and a separate patch extending into large wattles on the nape. All* Gracula *mynas have these wattles, but in other species they do not meet on the nape, as they do in the Nias form. This species is confined to a few small islands off north-western Sumatra.*

[*Gracula robusta*, Nias I, off NW Sumatra. Photo: Roland Seitre]

following the discovery that the type specimen had been misidentified. The White-faced Starling, together with the Bali Myna (*Leucopsar rothschildi*), is part of a clade which includes, in addition, four species which form a monophyletic group and now occupy a narrower genus *Sturnia*; these four are the Chestnut-tailed Starling (*Sturnia malabarica*), the White-headed Starling (*Sturnia erythropygia*), the Brahminy Starling (*Sturnia pagodarum*) and the White-shouldered Starling (*Sturnia sinensis*). An alternative arrangement would be to place all six species in *Sturnia*; but there is no strong indication that this is the best taxonomic solution, and it is considered better to retain the two monotypic genera. In an earlier discussion of speciation in Indian birds, S. D. Ripley and B. M. Beehler suggested as species pairs the Chestnut-tailed and White-headed Starlings, but also the Chestnut-tailed and White-faced Starlings; while the molecular data do, indeed, show the first two of these as sister-taxa within the same genus, it is not clear which species is the closest relative of the White-faced Starling.

A further two species previously placed in *Sturnus* appear in a clade together with the *Acridotheres* mynas, and are now, on the basis of the molecular data, assigned to the genus *Poliopsar*. These are the Red-billed Starling (*Poliopsar sericeus*) and the

The Asian-Australasian glossy starlings Aplonis *form the youngest branch of the tropical Asian clade, having separated about five million years ago. In the* ***Shining Starling****, the colour of the gloss varies between the races. In the nominate, the crown is glossed purple, and the throat and the long lanceolate feathers on the nape satin-green. These are structural colours, not produced by pigments. The colours, seen only from certain angles, are produced by the reflection and refraction of light passing through the outer keratin layer of the barbules, and striking melanin granules. The granules are arranged in patterns which seem to characterize different genera of starlings.*

[*Aplonis metallica metallica*, Australia. Photo: Roland Seitre]

Many passerines have a head pattern which includes a stripe through, above or below the eye. Starlings generally lack such features, with the striking exception of the ***Flame-browed Starling*** *of Sulawesi, which has a vivid reddish-orange band of feathers reaching from the nares over and behind the eye. In the race* centralis, *the superciliary stripe is yellow. The signal function of such plumage features has not been adequately studied, and descriptions of courtship and other social behaviour are still lacking for many species. The Flame-browed Starling's tail is strongly graduated, which may be an adaptation to reduce the negative impact of a long tail on flight efficiency.*

[*Enodes erythrophris leptorhynchus*, Lore Lindu National Park, Sulawesi. Photo: Pete Morris]

White-cheeked Starling (*Poliopsar cineraceus*). An alternative would be to include them in *Acridotheres*, but they appear somewhat different from the latter. Finally, two species which Feare and Craig had grouped in their genus *Sturnia* emerge as sister-taxa in the molecular phylogeny, with their closest relatives apparently the genus *Gracupica*; consequently, the Purple-backed Starling (*Agropsar sturninus*) and the Red-cheeked Starling (*Agropsar philippensis*) are now placed in the genus *Agropsar*, which was previously used by Wolters for these two species. If the assumptions of a molecular clock can be applied to these data, it would seem that the radiation within some genera, notably *Acridotheres*, is very recent. The extinct Reunion Starling (*Fregilupus varius*), confined to the island of that name, is evidently also derived from this Asian stock.

These new molecular studies provide valuable insights into the phylogeny of the starlings, and highlight the fact that the "traditional" classifications of the group, based on a limited set of morphological traits, probably used characteristics which have undergone independent adaptation in different lineages. Nevertheless, with only one specimen per taxon sampled in many cases, and with data which combine detailed genetic sequences from fresh material with partial sequences from museum specimens of varying age, it can be expected that there will be significant revisions of starling taxonomy in the future. A particularly interesting problem will be that of determining the origins of island endemics, and the sequence of colonization of islands in the Pacific region.

A degree of controversy has arisen in recent years regarding the genus name of the Australasian glossy starlings (*Aplonis*). The original name was first introduced by J. Gould at a meeting of the Zoological Society of London in July 1836. In early October of the same year, Gould's name was reported in print as "*Aplornis*" but a fortnight or so later it appeared as "*Aplonis*". The latter name was used almost universally until this problem in priority was pointed out in 1990. Currently, one school of thought considers *Aplonis* to be a junior synonym of *Aplornis*, which would thus have priority. The other main reading of this case is that *Aplonis* should be considered an incorrect subsequent spelling of *Aplornis*; as such, under the present Code, the overwhelming Prevailing Usage in favour of *Aplonis* would mean that this version should stand, but only if it can be attributed to the "publication of the original spelling". The debate rages on, and an application has been submitted to the International Commission on Zoological Nomenclature to conserve *Aplonis*. In these circumstances, the ICZN Code requires that the established name *Aplonis* continue to be used provisionally until such time as the Commission has taken its decision.

Morphological Aspects

Starlings range in body mass from about 35 g up to at least 290 g. None is truly tiny, nor are any of the family near the upper end of

Instead of eyestripes, some members of the genera Acridotheres *and* Sturnus *have bare skin behind and, often, in front of the eye. More extensive unfeathered areas on the head are found in representatives of the genera* Mino, Basilornis, Sarcops, Streptocitta, Gracula, Acridotheres, Leucopsar, Creatophora *and* Gracupica. *The bare yellow skin around the eye of the south-east Asian* ***Black-collared Starling*** *extends in a triangle behind the eye. The yellow coloration is probably caused by carotenoid pigments, which cannot be synthesized by birds, and must be acquired in the diet. The intensity of pigmentation may be a signal of the physiological and, perhaps, genetic "fitness" of the individual.*

[*Gracupica nigricollis*, Tsim bei Tsui, Hong Kong. Photo: John & Jemi Holmes]

the size range for passerines, although the Nias Hill Myna (*Gracula robusta*) and the Yellow-faced Myna (*Mino dumontii*) attain the size of some of the smaller *Corvus* crows. The sexes often differ, sometimes appreciably so, in size, with males larger than the females, but obvious sexual dimorphism in plumage is limited to some 25 species of the family total of 112. Plumage dimorphism occurs in eight members of the genus *Onychognathus*, in all three *Poeoptera* species, in the monotypic genera *Ampeliceps*, *Saroglossa*, *Cinnyricinclus*, *Creatophora*, *Grafisia*, *Notopholia* and *Speculipastor*, in both members of each of the genera *Agropsar* and *Poliopsar*, and in one species each of *Aplonis*, *Sturnia* and *Lamprotornis*. Only a few of the Sturnidae, all Asian, possess a prominent crest, these being the monotypic genus *Ampeliceps*, the four species in *Basilornis*, two species of *Aplonis* and six species of *Acridotheres*, while several other Asian species have long, erectile head feathers. All members of the family have ten primaries, the outermost of which is reduced to 10–40% of the length of the adjacent one, P9; they have six secondaries, three tertials, and twelve rectrices. As with other bird families, the wing shape is related to habitat and flight requirements, with pointed wings typical of fast fliers in open country, and of long-distance migrants, whereas shorter and more rounded wings are characteristic of birds inhabiting forest and dense vegetation.

Several *Lamprotornis* species, notably the Splendid Glossy Starling (*Lamprotornis splendidus*), have indentations or deep notches on the inner margins of the outer three or four primary feathers. This causes the wings to produce a loud swooshing sound in flight, which is often a useful field character for the human observer. Whereas some other bird species, such as the Cape Sugarbird (*Promerops cafer*), have modified primary wing feathers restricted to males, and the sound produced by them forms an element in the courtship display, the wing noise made by these starlings is apparently an involuntary accompaniment to normal flight, and there is no sexual dimorphism in wing structure; in this case, the sounds produced may have a role in flock cohesion. It is, however, puzzling that sympatric species with similarities in ecology may differ in this respect: for example, wing notches are present in the Cape Glossy Starling (*Lamprotornis nitens*) and the Greater Blue-eared Starling (*Lamprotornis chalybaeus*), yet are absent in the Lesser Blue-eared Starling (*Lamprotornis chloropterus*). No Asian starlings have been described as possessing wing notches, although noisy flight is a feature mentioned by field observers for both the Southern Hill Myna (*Gracula indica*) and the Sri Lanka Hill Myna (*Gracula ptilogenys*).

Greatly extended tail feathers, with the tail longer than the wing, are a characteristic of ten African sturnids and nine Asian ones. These include some species which spend much of their time on the ground, such as the Long-tailed Glossy Starling (*Lamprotornis caudatus*) and Meves's Long-tailed Starling (*Lamprotornis mevesii*) of the African savanna woodlands. Aerodynamic theory predicts that a long tail can significantly reduce flight efficiency, but that greatly narrowed rectrices have the least impact, with a graduated tail the next best option. Only the White-eyed Starling (*Aplonis brunneicapillus*), an Asian forest bird and island endemic, has two thin, protruding tail-streamers. All the other long-tailed species have a symmetrically graduated tail, with the central feathers the longest and the outermost feathers the shortest. Sometimes the wing and tail proportions vary regionally, as with the Red-winged Starling (*Onychognathus morio*), Ethiopian populations of which have a longer tail which routinely exceeds the wing in length. There is no obvious ecological explanation for this variation, as four other members of the same genus occur in Ethiopia, of which the White-billed Starling (*Onychognathus albirostris*) is notably short-tailed, whereas the Bristle-crowned Starling (*Onychognathus salvadorii*) and Slender-billed Starling (*Onychognathus tenuirostris*) are very long-tailed, and the Somali Starling (*Onychognathus blythii*) has a long, graduated tail.

Coloured patches in the primary wing feathers are rufous in the case of female *Cinnyricinclus* and *Poeoptera* species and in both sexes of all except one *Onychognathus* species. In the latter instance the single exception is the Pale-winged Starling (*Onychognathus nabouroup*), the wing patch of which appears white in flight, since the inner vanes of the feathers are creamy white and only the narrow outer vane is rufous. The extent of the coloration on the individual feathers varies among different species, so that in some cases the field impression is of a large coloured area with a narrow black border at the feather tips, whereas in others the patch appears more centrally positioned. Pale patches in the wing, visible in flight, are found also in the monotypic genera *Neocichla*, *Hartlaubius*, *Saroglossa*, *Speculipastor* and *Ampeliceps*, in the three *Mino*, the five *Gracula* and all ten *Acridotheres* mynas, in both species of each of the genera *Agropsar* and *Gracupica*, in the Red-billed Starling in the genus

The genus Agropsar *has often in the past been subsumed in* Sturnus. *On the basis of their small size, nectarivorous diet and arboreal habits, the Red-cheeked* (A. philippensis) *and* ***Purple-backed Starlings*** *were recently separated from* Sturnus, *and assigned to the resurrected genus* Sturnia. *But more recently still, molecular studies have found no support for a broad genus* Sturnia. *The Purple-backed and Red-cheeked Starlings emerged as sister-taxa in a molecular phylogeny, and were placed alone in the genus* Agropsar. *They may form a superspecies. Their closest relatives appear to be members of the genus* Gracupica.

[*Agropsar sturninus*, Otindag Sandy Land, Inner Mongolia, China. Photo: Zhao Chao]

A few species of sturnids have been found to have a brush-tipped tongue, a feature typical of nectarivorous birds such as sugarbirds (Promeropidae) and honeyeaters (Meliphagidae). This has been described for the Madagascan Starling (Hartlaubius auratus) *and some Asian species, including the* ***Brahminy Starling****. But the Brahminy Starling also forages on the ground, and shows adaptations for opening the bill forcefully when probing or prying, a style of feeding fully developed in other genera, particularly* Sturnus. *The Brahminy Starling has a long wispy crest formed by elongate and hackled crown feathers. The feathers of the nape and upper breast are also hackled.*

[*Sturnia pagodarum*, Bangalore, Karnataka, India.

Poliopsar, and in the Chestnut-bellied Starling (*Lamprotornis pulcher*). White tips on the outer tail feathers, also conspicuous in flight, are found in nine *Acridotheres* species, two other Asian sturnids, namely the White-shouldered Starling and Asian Pied Starling, and the Madagascan Starling. A pale rump patch, contrasting with the back plumage, is much less common in this family, being found only on the Wattled Starling, the Vinous-breasted and Black-winged Mynas, all three species of *Mino* and both species of *Gracupica*, and the Apo Myna (*Basilornis mirandus*), the White-cheeked Starling and the Purple-backed Starling. The significance of such "flash coloration" is obscure, as many highly social starlings which flock regularly, such as the Common Starling, lack any of these signal features. Human appreciation of the plumage of many starlings, however, probably differs markedly from these birds' own perceptions, since recent studies have revealed that Common Starlings have well-developed detection of light in the ultraviolet range. This ability may be of assistance to the birds when searching for food, especially ripening fruit, but it could also provide cues from the plumage which are of value in social behaviour.

Wing moult follows the descendant pattern typical of most passerine families, the feathers being replaced in sequence from the inner ones outwards. The primary moult of the Wattled Starling is frequently suspended, this apparently in association with the species' nomadic movements (see Movements), and this has been reported also for the Rose-coloured Starling (*Pastor roseus*) and some of the migratory species in Eurasia. The Amethyst Starling exhibits an interesting pattern over its extensive range, where the timing of the moult period appears to be more constant among different populations than the breeding season or seasonal movements. Thus, in different regions, the birds may breed, moult and then migrate, while others breed, migrate and then moult, and yet others moult before migrating to their breeding areas. This colourful species is well represented in many museum collections, and its moult pattern was established by M. Traylor from a careful examination of hundreds of specimens for which accurate date and locality information was available. This is a timely reminder of the valuable biological information which can be gleaned from well-curated museum collections.

For most species, the typical pattern of feather replacement seems to be a complete moult at the end of the breeding season. Nevertheless, for some African starlings such as the Red-winged Starling, which may have several broods in the course of a single season, an overlap between moult and breeding occurs regularly while the later broods are still being fed. Such overlap is associated with a reduction in the number of new wing feathers growing out at the same time, typically with only one actively growing feather in each wing. The timing of moult may also differ between the sexes in such cases, females taking charge of the last brood and deferring their moult, whereas males start the moult and abandon parental care. Among African passerines, this sexual dimorphism in moult appears to be correlated with sexual dimorphism in plumage, and may therefore be less common among the monomorphic starlings. The new generation of fledglings has either a complete or a partial post-juvenile moult, with some apparent taxonomic correlation; many Eurasian starlings have a complete first moult, whereas this moult tends to be partial among African species, with the exception of the Wattled Starling. For a number of the species, however, adequate information on the moult sequence is still lacking.

Our understanding of the hormonal control of moult in passerine birds in general remains surprisingly poor. Experimental manipulation of the photoperiod to mimic seasonal changes in daylength suggested that periodic events in the annual cycle of Common Starlings, such as moult, breeding and migration, were under the control of circannual rhythms, inherited patterns the precise timing of which is set by particular environmental stimuli termed *Zeitgeber*. E. Gwinner and his colleagues even induced several moult cycles within a single year among captive Common Starlings by producing, in the laboratory, an artificially accelerated cycle of the appropriate annual changes in daylength. Experiments with the male hormone testosterone showed that this delayed the onset of moult in male Wattled Starlings and Common Starlings, and could also lead to interruption of the moult. A preliminary conclusion was that, for male birds, moult might be retarded by testosterone and stimulated by thyroxine, produced in the thyroid gland, so that moult would be regulated by a push–pull action of these two hormones, within the limits of a "moulting window", the fixed period in the annual cycle during which moult could occur. In field studies in Kenya, it was found that male Greater Blue-eared Starlings did not moult during the period of peak levels of testosterone and luteinizing hormone,

The Acridotheres *mynas are part of a clade of Eurasian genera that includes a broadly defined* Sturnus *and the Bali Starling* (Leucopsar rothschildi), *together with the Afrotropical Wattled Starling* (Creatophora cinerea). *The* ***White-vented Myna*** *is a typical blackish myna, with a prominent frontal crest and elongated crown feathers. The* ***Vinous-breasted Myna****, on the other hand, is atypically small, with pale plumage, although like other* Acridotheres *mynas its forehead and crown feathers are hackled and elongate. The Vinous-breasted Myna, along with the Black-winged Myna* (A. melanopterus), *is sometimes placed in the genus* Sturnus, *but both appear behaviourally and vocally closer to the mynas. A molecular phylogeny for the Euasian radiation of Sturnidae has reinforced the inclusion of the Vinous-breasted and the Black-winged Myna among the ten* Acridotheres *species. Nine of these have white tips on the outer tail feathers, which are conspicuous in flight. All* Acridotheres *species have pale patches on the wing, which are also visible in flight.*

[Above: *Acridotheres javanicus*, Bangkok, Thailand.

The plumage of the male ***Somali Starling*** *is mostly uniformly purple-black. The female differs in having the head, throat and breast plain ash-grey. Although male sturnids are sometimes appreciably larger than females, obvious sexual dimorphism in plumage is limited to some 25 species out of the family total of 112.* Onychognathus *starlings range from Africa into the Arabian Peninsula. Nine of the eleven species are sexually dimorphic as adults, the females regularly having a grey head. Juveniles resemble the adult male, and have uniformly dark plumage, the first grey feathers not appearing on the heads of the young females until at least six months after fledging. Among African passerines, species that are sexually dimorphic in plumage may also differ sexually in the timing of the moult, with females taking charge of the last brood and deferring their moult, whereas males start their moult earlier and abandon parental care. Greatly extended tail feathers, with the tail longer than the wing, are a characteristic of ten African and nine Asian sturnids. Sometimes wing and tail proportions vary regionally, as with the Red-winged Starling* (O. morio)*, Ethiopian populations of which have a tail which routinely exceeds the wing in length. There is no obvious ecological explanation for this, since of four other members of this genus that occur in Ethiopia, the Somali Starling, the Bristle-crowned Starling* (O. salvadorii) *and the Slender-billed Starling* (O. tenuirostris) *are all long tailed, whereas the White-billed Starling* (O. albirostris) *is notably short-tailed.*

nor did females during the peak levels of luteinizing hormone and 17-β-estradiol. At the same study site, however, there was no detectable cyclic variation in the levels of these hormones in Rüppell's Glossy Starling (*Lamprotornis purpuroptera*), yet moult was well synchronized in the population, despite considerable individual variation in blood hormone levels. More recently, experimental work on the Common Starling has demonstrated that neither changes in photoperiod nor the regression of the gonads, both of which normally occur at the end of the breeding season, were regularly linked to the start of the moult. Nevertheless, the start of the moult always followed a period when the production of the hormone prolactin had reached a peak. In the normal annual cycle, this would coincide with the end of the phase of parental care, when all breeding activity is tailing off. It remains to be seen if these findings are of general application, and not specific to the Common Starling; prolactin levels were not monitored during the earlier investigations.

Many starlings have strikingly iridescent plumage, the African glossy starlings producing stunning combinations of green, blue and purple. It has been known for a long time that these are structural colours, not produced by pigments. In fact, one of the early applications of electron microscopy was to describe the internal structure of iridescent feathers in different bird families, including a selection of starlings. The only pigment present is melanin, concentrated into discrete granules, which may be round or flattened and which, in the case of some African starlings, have internal air spaces. Within the barbules of the feather, these granules are arranged in patterns which seem to characterize different genera of starlings. The colours to be seen from a particular position can be defined in simple physical terms by the reflection and refraction of light passing through the outer keratin layer of the feather barbule, and then striking the melanin granules.

The realization that bird vision extends into the ultraviolet region of the spectrum has led to a reassessment of the plumage patterns of some species from the bird's eye view. For the Common Starling, some experimental work suggests that individual plumage differences visible only in the ultraviolet range may influence mate selection. Future research on the visual signals used by other starling species will now have to look beyond the mere human range of vision.

No starling species exhibit a seasonal alternation of plumage as a result of a moult. Common Starlings in fresh plumage do, however, have pale tips on the feathers, producing a heavily speckled pattern, but, as these pale tips gradually disappear through abrasion, the birds become more uniformly dark in appearance. The freshly moulted feathers of Spotless Starlings, on the other hand, display a dull greyish "bloom", and this also wears away to reveal the spectacular iridescence of the adults' plumage. Juveniles of all starlings are duller than the adults in appearance, generally lacking any iridescence, and are often spotted on the ventral surface. In the genus *Poeoptera*, juveniles resemble the female, and young males therefore initially have a chestnut patch in the primary feathers; at the first complete moult, the male replaces the wing feathers with those typical of the adult male, lacking a coloured patch. Nine of the eleven *Onychognathus* species are sexually dimorphic as adults, the females having a grey head. In this case, however, the juveniles resemble the adult male and have uniformly dark plumage, the first grey feathers on the head of the young females not appearing until at least six months after fledging.

Compared with most other passerine bird families, a high proportion of starlings have a red, yellow or creamy-white iris, and the juveniles of all such species initially have a dark eye. The eye colour of the juveniles usually changes by the end of the first year, although this process may take longer in some species. The pigments or structures responsible for iris coloration have not been investigated in detail; in the African Pied Starling (*Lamprotornis bicolor*), it appears that pteridines are responsible for the white appearance of the adult iris. Since human observers can recognize age categories on the basis of iris coloration, it is likely that the latter plays some role in the social organization of those species having coloured eyes. In addition, changes in pupil size, which can be under voluntary control in birds and not influenced solely by the autonomic nervous system, result in the display of a larger or smaller area of coloured iris, depending on whether the pupil is contracted or dilated, and this may serve as an important close-range signal during interactions between individual birds in a flock. Indeed, some field observations suggest that dominance relationships may be indicated by such subtle signals. For example, during food exchanges, or allofeeding (see

Following molecular studies, some Afrotropical glossy starlings have been reassigned to different genera. The ***Cape Glossy Starling*** *however remains in an expanded* Lamprotornis. *Several* Lamprotornis *species have deep notches on the inner margins of the outer primaries. This causes the wings to produce a loud swooshing sound in flight. There is no sexual dimorphism in wing structure; the wing noise is apparently an involuntary accompaniment to normal flight, and may have a role in flock cohesion. Sympatric species with similarities in ecology may differ in this respect. Wing notches are present in the Cape Glossy Starling and the Greater Blue-eared Starling* (L. chalybaeus), *yet absent in the Lesser Blue-eared Starling* (L. chloropterus).

[*Lamprotornis nitens*, Bube, S Zimbabwe. Photo: Warwick Tarboton]

While some Lamprotornis *species, such as the Cape Glossy Starling* (L. nitens), *have predominantly or entirely glossy plumage, a number of* Lamprotornis *starlings combine glossy, metallic upperparts with brown or chestnut underparts. For example, the crown, chin, throat and upper breast of* ***Shelley's Starling*** *are a glossy dark purple, its upperparts dark glossy blue, its wing bronze-green and its tail glossy blue-green. Its underparts, from the lower breast down, are uniformly dark rufous-brown. Sexes are alike in Shelley's Starling, but in some* Lamprotornis *species the female, though similar, may be duller.*

[*Lamprotornis shelleyi*, Negele, Ethiopia. Photo: Ketil Knudsen]

General Habits), involving African Pied Starlings, the donor bird contracts the pupil and displays a large area of white iris, whereas the individual accepting the food, in a juvenile-like begging posture, dilates its pupil and minimizes the area of coloured iris on display. In the case of the Black-bellied Glossy Starling, changes in eye colour have been observed while the bird is held in the hand: the yellow eye facing the observer is apparently flushed with blood and turns red within a few seconds, while the eye on the opposite side of the head remains unaffected. Male Black-bellied Glossy Starlings, incidentally, appear to retain red eyes during breeding activity under natural conditions. Such spontaneous eye-colour changes have not been observed for any other yellow-eyed glossy starlings when they are handled. This is an area of study in which the filming of the behaviour of captive groups, or of individuals which are habituated to the close approach of the human observer, could be very revealing. The sexes of Common and Spotless Starlings differ in iris colour. Males of these two species have the iris largely brown, whereas the iris of females bears a pale outer ring, this difference providing a useful sex-recognition identifier in population studies.

Starling bills vary from being an elongated probe to being a powerful, hooked structure suggesting predatory habits. In a few

A large starling with predominantly glossy plumage, the ***Long-tailed Glossy Starling*** *has an extremely long, strongly graduated, supple tail. The rectrices are paired in step-like fashion. Although the sexes are similar in plumage, the male is visibly larger than the female. Like Meves's Long-tailed Starling* (Lamprotornis mevesii) *with which it forms a superspecies, the Long-tailed Glossy Starling spends much of its time on the ground. Both species are found in open, park-like savanna woodland; the Long-tailed Glossy Starling may also be found in farmland and well-wooded residential areas. Greatly extended tail feathers are a characteristic of ten African sturnids, and nine Asian ones.*

[*Lamprotornis caudatus*, Western Division, Gambia. Photo: Dick Forsman]

Although it has some bronze sheen on its back and rump, ***Fischer's Starling*** *generally lacks the metallic gloss of most of its congeners. Its crown, nape and upperparts, chin, throat and breast are dull ash-grey, its flight-feathers and tail dull bronzy green, and its belly, flanks, thighs and undertail-coverts white. Fischer's Starling has sometimes been placed in a separate genus,* Cosmopsarus, *along with both the similarly dull, uniformly grey Ashy Starling* (Lamprotornis unicolor), *which has an oily green sheen on the wing and tail feathers, and the highly distinctive, colourful and glossy Golden-breasted Starling* (L. regius), *with which Fischer's Starling sometimes associates.*

[*Lamprotornis fischeri*, Samburu National Park, Kenya. Photo: Dave Richards]

cases, the Bristle-crowned Starling being one example, the feathers at the base of the bill are directed forwards, covering the nostrils, an arrangement typical of many corvids. The bill is always proportionately narrow at the base, unlike the wide, flattened bill of fly-catching passerines. Although the bill of many sturnid species is of a uniformly dark colour throughout life, as typified by, for instance, most red-winged starlings in the genus *Onychognathus*, there are some exceptions, such as the White-billed Starling, and others in which age-related or seasonal changes in bill coloration occur. In the African Pied Starling, for example, the white at the gape and base of the bill which characterizes the nestling is retained for much of the first year, during the juvenile stage. By the second year, both the gape and the base of the lower mandible have turned yellow, and during that year the yellow coloration advances progressively farther along the lower mandible, so that adults and subadults can be distinguished by this feature. The bill of the Common and Spotless Starlings is dark brownish-black in the non-breeding period, but it becomes yellow before and during the breeding season, at which time the adults of the two sexes can be distinguished by the colour of the base of the bill, males having a bluish bill base and females a pinkish one.

Jaw musculature and skull structure are influenced primarily by feeding ecology. In their study of the foraging behaviour of the Sturnidae, M. S. Dubale and G. Patel linked these anatomical details to feeding behaviour for the Common Myna (*Acridotheres tristis*) and the Rose-coloured Starling. Meanwhile, W. J. Beecher, having dissected a number of starling species, found that the generalized arrangement, typical also of many Old World insectivorous families such as the sylviid warblers, has a series of parallel muscles emphasizing adduction rather than protraction. The skull is broad, with lateral extensions, or "wings", on the ectethmoid bone. This condition was found in members of the Afrotropical genera *Cinnyricinclus*, *Grafisia*, *Lamprotornis*, *Onychognathus*, *Poeoptera* and *Speculipastor*, as well as in the Asiatic *Aplonis*, *Basilornis*, *Gracula*, *Mino*, *Sarcops* and *Streptocitta*. In the specialized Grosbeak Starling (*Scissirostrum dubium*) the protractor of the quadrate bone is greatly enlarged, as are its antagonistic muscles attached to the pterygoid and palatine bones. This arrangement resembles that typical of the woodpeckers (Picidae), which evidently provides a muscular shock-absorber, protecting the brain from concussion when the bill is used to strike a hard surface. Other starlings show progressive adaptations for opening the bill forcefully when probing or prying. This involves development of the protractor muscles for elevating the upper mandible, and depressing the lower mandible, and Beecher noted it in two Asian species, the Rose-coloured Starling and Brahminy Starling, and in the Madagascan Starling. Although the muscles of these species are modified, the anterior part of the skull is still broad. He identified another group of starlings in which the protractor muscles are further enlarged, and there is a narrowing of the skull and reduction of the ectethmoid wings; this group included several Eurasian species in the *Acridotheres* and *Sturnus*

Sole species in the genus Grafisia, *the* ***White-collared Starling*** *is sexually dimorphic. The male is uniformly glossy blue-black, except for a white patch on the upper breast, which ends sharply in line with the wing. The female is charcoal-grey without gloss, but with feathers from the crown to rump tipped blue-black, and with dull black wings and tail. Both sexes have a yellow iris. Compared with most other passerine families, a high proportion of starlings have a red, yellow or creamy-white iris, and the juveniles initially have a dark eye. The eye of the juvenile White-collared Starling is dark brown. Juvenile eye colour usually changes by the end of the first year, although this may take longer in some species.*

[*Grafisia torquata*, Ngaoundaba, Cameroon. Photo: Ron Hoff]

clade, as well as their African relative *Creatophora*. The probing style of feeding is most highly developed in three species, the Common Starling, the Spotless Starling and the White-cheeked Starling. In these sturnids, not only are the protractor muscles very strongly developed but, in addition, the skull is greatly narrowed, with the ectethmoid no longer in contact with the jugal bones, and the eye can be moved forwards to peer down along the line of the bill.

A small number of species in the Sturnidae have been found to have a brush-tipped tongue, a feature typical of nectarivorous birds such as the southern African sugarbirds and the mainly Australasian and Oceanian honeyeaters (Meliphagidae). The tongue of the Reunion Starling, sadly now extinct (see Status and Conservation), has a distinctive frayed tip, and a similarly brush-tipped tongue has been described for the extant Madagascan Starling and some Asian species, such as the Brahminy Starling.

The presence or absence of rictal bristles at the base of the bill was formerly cited as a character which separated the starlings into distinct groups. The functional significance of these structures, however, remains unclear. Rictal bristles are especially prominent in some insectivorous birds, such as the nightjars (Caprimulgidae) and the muscicapid flycatchers, but they are conspicuous also in the frugivorous barbets (Capitonidae). Anatomically, they represent feather shafts lacking vanes, typically innervated by tactile sensory neurones. These bristles can in most cases be moved, and at least in the case of the nightjars, and probably also other birds, the best current explanation seems to be that they serve to protect the eyes.

Possession of a prominent crest of feathers is largely restricted to the Asian genera *Basilornis* and *Acridotheres*, but is a feature also of two species of *Aplonis* and the Bristle-crowned Starling of East Africa. Several other species, such as the Bali Myna, the Rose-coloured Starling and the Golden-crested Myna (*Ampeliceps coronatus*), have elongated head feathers which they may erect to form a conspicuous crest during display. Whereas many passerines have a head pattern which includes a stripe through, above or below the eye, such features are generally not present on starlings, although some members of the genera *Acridotheres* and *Sturnus* have bare skin behind and, often, in front of the eye, as does the Wattled Starling. A striking exception is the Flame-browed Starling (*Enodes erythrophris*) of Sulawesi, with its vivid reddish-orange stripe above the eye. The signal function of these plumage features has not been adequately explained, as descriptions of courtship and other social behaviour are still lacking for many of these species.

More extensive bare, unfeathered areas on the head are found in representatives of the genera *Mino*, *Basilornis*, *Sarcops*, *Streptocitta*, *Gracula*, *Acridotheres*, *Leucopsar*, *Gracupica* and *Creatophora*. Colour changes of the bare areas, resembling blushing, may be associated with blood flow in some of these species. In many cases, the yellow coloration of the skin is probably caused by carotenoid pigments, a group of pigments which has been the focus of recent research interest, as they cannot be synthesized by birds but, instead, require the acquisition of pigments or their precursors in the diet. Thus, it is argued that the intensity of carotenoid pigmentation is an accurate signal of the physiological and, perhaps, genetic "fitness" of the individual and could be a factor influencing the female's mate choice. This suggestion awaits experimental testing with regard to starlings. The bluish bare skin around the eyes of the Bali Myna has been confirmed as being an example of structural coloration, whereby arrays of parallel collagen fibres in the dermis of the skin produce the blue coloration by coherent scattering of light; presumably, the same explanation applies in the case of the White-faced Starling, which also has bluish bare skin around the eye. It is now evident that collagen fibres may enhance the coloration produced by carotenoid pigments in other bird species, and this should be examined with regard to other starlings, too. In addition to these permanent features, the facial feathers of Common Starlings often become abraded during the breeding season, producing bare areas around the base of the bill, sometimes extending backwards to as far as the eyes. This may be a result of the frequent open-bill probing involved in procuring food for the young. Exceptionally, Common Mynas lose the feathering from most of the head, so that the individual is totally yellow-headed, but the reason for this is unknown, and it may prove to be a pathological condition.

The starlings with bare facial skin are, with one exception, found in Asia. The single exception is the Wattled Starling, but this species, as noted above (see Systematics), is evidently of Asian origin. It is the only species which exhibits a seasonal change in either the extent or the coloration of the patches. With this species, the bare areas develop on adult males in breeding

The bills of many sturnid species are of a uniformly dark colour throughout life. The bill of the adult ***Magpie Starling*** *is black, whereas that of the juvenile is brown. In other species, age-related or seasonal changes in bill coloration occur. In the African Pied Starling* (Lamprotornis bicolor), *for example, the white at the gape and base of the bill, which characterizes the nestling, is retained for much of the first year. By the second year, both the gape and the base of the lower mandible have turned yellow, and during that year the yellow coloration advances progressively along the lower mandible, so adults and subadults can be distinguished by this feature.*

[*Speculipastor bicolor*, N Kenya.

Sharpe's Starling *is found in montane forests, where it forages mainly in the canopy. Leg proportions of starlings differ according to the species' lifestyle. Tree-dwellers like* Pholia *and* Poeoptera *hop along on their relatively short legs. Those that usually forage on the ground walk or even run, and have longer legs. There are minor differences in leg musculature in different starling species according to the style of locomotion, but these are apparently not informative of taxonomic relationships. Although all the species in* Pholia *and* Poeoptera *are forest frugivores from the same region of Africa, differences such as sexual dimorphism in* Poeoptera *but not* Pholia *suggest that they should not be treated as congeneric.*

[*Pholia sharpii*, Ruhija, Uganda. Photo: Pete Morris]

condition, under the influence of male hormones, notably testosterone. The process has attracted the attention of physiologists, because of the apparent parallels with baldness in human males. There is considerable individual variability in the development of the pendulous wattles. Both sexes retain a small area of naked skin behind the eye at all times, and old female Wattled Starlings sometimes also develop featherless and pigmented areas on the head. Females of all starling species, however, do acquire a typical brood patch, losing much of their ventral feathering to produce an area of highly vascularized skin during the incubation period. This is a very useful feature for confirming the sex and breeding status of a starling in the hand, since extensive and vascularized brood patches have not been found on males of this family, even when the males cover the eggs during their incubation stints. It appears, in fact, that male sturnids do not incubate in the strict sense of the word, but that their sitting on the eggs helps to reduce heat loss during the female's absence.

Leg proportions of starlings differ according to the species' lifestyle, whether it is more arboreal or more terrestrial. Those which usually forage on the ground walk or even run, and have longer legs, whereas tree-dwellers hop, moving their relatively shorter legs simultaneously. The leg musculature is naturally adapted to the style of locomotion, and there are minor differences in the proportions and insertions of particular muscles in different starling species. These are significant from a functional viewpoint, but are apparently not informative of taxonomic relationships.

Habitat

With a natural range extending from the Arctic Circle southwards to beyond the tropics, where some species range above 4000 m in the mountains, starlings are clearly not narrow habitat specialists. Members of the Sturnidae inhabit forest and forest edge, savanna and other grasslands, macchia, semi-arid to desert scrubland, orchards and plantations, and commonly enter gardens in villages, towns and cities. Only the barren sandy wastes of the deserts in north Africa and Asia do they skirt or fly over without stopping off. They must have colonized many of the Pacific Ocean islands where they are now found by making over-water flights, and several regular migratory routes of starlings cross large areas of open sea (see Movements).

Evergreen forest is the principal habitat for starlings in Asia, where 39 species are categorized as forest birds, compared with 24 in open woodland, agricultural and urban areas, and only a few, such as the Rose-coloured Starling, regularly occurring in steppe or treeless grassland regions. For African starlings, on a continent with a long history of arid periods, there are 13 true forest species; the majority of sturnids in this region, 32 species, including the Madagascan Starling, are found in savanna woodland, and only the African Pied Starling and the Wattled Starling are typical of open grassland over a large part of their ranges.

Forest starlings show a clear division into species inhabiting lowland forest and those preferring the high mountain forests, yet it is surprising that there is none in the highland forests of New Guinea. On the Philippine island of Mindanao, the Asian Glossy Starling (*Aplonis panayensis*) and the Coleto (*Sarcops calvus*) occur in the lowlands, with the Apo Myna restricted to forests above 1200 m. Some African members of the family, such as the White-crowned Starling (*Lamprotornis albicapillus*), occur in relatively arid thornveld, and some of the cliff-nesting *Onychognathus* species range into desert areas in Africa and in the Arabian Peninsula.

Many sturnid species have proved well capable of adapting to environments modified by humans. A good example of this can be seen in the heavily populated regions of Asia, where numerous starlings are today closely associated with human activity, and it is difficult to visualize what habitats they may have occupied previously.

General Habits

While some Asian starlings have been sighted only singly or in pairs, it is possible that this, rather than representing a distinctive type of social organization, may relate more to the difficulty of observing birds in the forest canopy, and perhaps the current rarity of the species concerned. Nevertheless, some species, such as

*Changes in the eye colour of the **Black-bellied Glossy Starling** have been observed while the bird is held in the hand. The yellow eye facing the observer is apparently flushed with blood, and turns red within a few seconds, while the eye on the opposite side of the head remains unaffected. Male Black-bellied Glossy Starlings appear to retain red eyes during breeding activity under natural conditions. Such spontaneous eye-colour changes have not been observed for any other yellow-eyed glossy starlings when they are handled. Since human observers can recognize whether a starling is subadult or adult on the basis of iris coloration, it is likely that this plays some role in the social organization of those species with coloured eyes. In addition, changes in pupil size, which can be under voluntary control in birds and not influenced solely by the autonomic nervous system, result in the display of a larger or smaller area of coloured iris, depending on whether the pupil is contracted or dilated. This may serve as an important close-range signal during interactions between individual birds in a flock. Some field observations suggest that dominance relationships may be indicated by such subtle signals. For example, during food exchanges, involving African Pied Starlings* (Lamprotornis bicolor), *the donor bird contracts the pupil and displays a large area of white iris, whereas the individual accepting the food, in a juvenile-like begging posture, dilates its pupil and minimizes the area of coloured iris on display.*

Most members of Sturnidae are sociable, and found in flocks of varying size through much of the year. The ***Golden-breasted Starling*** *often forages in small groups; it also feeds in loose association with Fischer's Starling* (Lamprotornis fischeri). *Flocks may offer their members greater security from predators, reducing the statistical likelihood of an individual becoming a victim, and providing more eyes to look out for threats. Some large sturnid species such as the Common Myna* (Acridotheres tristis) *and the Common Hill Myna* (Gracula religiosa) *are more often found foraging in pairs, and may maintain a rigid pair structure throughout the year. But these species may still join communal roosts, which can contain tens to thousands of individuals.*

[*Lamprotornis regius*, Negele, Ethiopia. Photo: Ketil Knudsen]

the Common Myna and the Common Hill Myna (*Gracula religiosa*), may maintain a fairly rigid pair structure throughout the year. Most members of the Sturnidae, however, associate in flocks of varying size through much of the year, and even when breeding they are often clustered or even densely colonial, with nests less than 2 m apart.

Mixed-species flocks, which can include birds from several different families, occur in foraging associations of both frugivores and insectivores. Such flocks seem to offer their members greater security from predators in that, statistically, an individual's chances of being the victim of a predator are reduced when alternative prey is close at hand, and also because many eyes provide a greater chance that the predator will be spotted before it can launch an attack. Flocking may arise also through "local enhancement", whereby those birds which are already feeding attract additional individuals to what are usually patches of superabundant food. Starlings have not often been recorded as participants in mixed-species flocks of insectivorous birds. In South Africa, the Cape Glossy Starling was an occasional flock-member in both mixed woodland and acacia (*Acacia*) woodland, while the Purple-headed Glossy Starling joined both insectivorous and frugivorous flocks in Gabon. Four sturnids characterized as "gleaners" were noted as members of insectivore flocks in South-east Asian forests; these four were the Asian Glossy Starling, the Golden-crested Myna, the Common Hill Myna and the Purple-backed Starling. Farther east, on San Cristobal, in the Solomon Islands, the Makira Starling (*Aplonis dichroa*) joined flocks in which monarch-flycatchers (Monarchidae) were core members.

In Africa, observations in Gabon of frugivorous birds in fruiting trees, an assemblage which included Purple-headed Glossy and Splendid Glossy Starlings, green pigeons (*Treron*), hornbills (Bucerotidae), turacos (Musophagidae) and bulbuls (Pycnonotidae), indicated that raptors flying over the canopy tried to attack birds in such mixed groups more often than they did individuals in single-species flocks of frugivores, whereas far fewer attacks were made on the flocks of insectivorous birds foraging in the same forests at lower levels. This implies that the protective function of these flocks may not apply equally to different groupings of species.

Particularly during the non-breeding season, starlings gather at night in roosts which may encompass only small groups, but often thousands or even hundreds of thousands of birds drawn from a wide area. Dry-season roosts of Splendid Glossy Starlings in Gabon are reported as holding tens of thousands of individuals, and some of the rural roosts of Common Starlings in Europe have been estimated to number some two million birds, while in Israel they are even estimated at up to eight million. For most starling species, nothing is known about the internal organization of these roosts: information is lacking on how closely the birds are clustered together, whether individuals preferentially roost near familiar conspecifics, and whether the sexes and the age-classes are separated.

Studies of the Common Starling have revealed that the huge winter roosts of this species are by no means a random accumulation of individuals, as there are significant associations between birds which sing a common dialect and perch close together each night. In these large winter roosts of Common Starlings there is also segregation of both sexes and ages, adult males being predominant in the centre and younger females resorting to more peripheral parts of the roost site. This distribution results from competition, involving posturing and overt aggression among individuals, for the available perching spaces. Departure for the feeding areas during the early morning is a complex affair, major exoduses of starlings from the roost taking place at approximately three-minute intervals, the adult males departing first and younger females later. Roosts are often regarded as secure sleeping places, where the birds are safe from attack by predators. For this species, however, temperature also plays a role. In rural woodlands the Common Starlings tend to select warmer, less windy locations, and urban localities are significantly warmer than surrounding rural areas during the coldest winter months; for starlings needing to forage every day in order to maintain their energy balance, this can be crucial for their survival. Under extremely cold conditions, the usual inter-individual distance maintained by roosting individuals is reduced and the birds sometimes huddle together.

The complex aerial gyrations of Common Starlings prior to settling in the roost certainly look like a predator-avoidance strategy, and the extraordinary patterns created by these flocks, and

Outside the breeding season, ***Common Starlings*** *will gather from a wide area to join communal roosts. The birds may come from a radius of more than 50 km, and on occasions up to 120 km. Common Starlings are considered one of the most abundant bird species in the world, and the roosts can include thousands or even hundreds of thousands of birds. Some rural roosts of Common Starlings in Europe have been estimated to contain more than two million birds. Similarly, dry-season roosts of Splendid Glossy Starlings* (Lamprotornis splendidus) *in Gabon are reported as holding tens of thousands of individuals. The extraordinary patterns created by flocks of Common Starlings as they manoeuvre about have led mathematicians to develop numerical models to try to understand them. Their work indicates that the ability of all the birds in the flock to act as one, turning together on an instant without collisions, could emerge from simple local rules of interaction between the individual birds. The implication of one study (which does not mention starlings) is that rather than monitoring all the birds within a given radius, each bird keeps track of the current positions of six or seven individuals which are separated from it by a fixed number of other birds. The critical distance is thus topological, dependent on the structure of the surroundings, and not a simple linear measure of separation. Modelling of the process suggests that flocks organized on this principle are much more stable against perturbations, such as the attack of a predator, and are much less likely to split up and leave some individuals temporarily isolated and vulnerable.*

[*Sturnus vulgaris vulgaris*, Djerba, Tunisia. Photos: Manfred Pfefferle]

Flocking increases the chances of individual survival, and also enables smaller birds to use their numbers to drive away predators. ***Common Starlings****, here seeing off a male Western Marsh-harrier* (Circus aeruginosus)*, give a short, metallic "chip" call on sighting a predator. Studies of the Common Starling have revealed that their huge winter roosts are not random accumulations of individuals. There are significant associations between birds which sing a common dialect and perch close together each night. Roosts are often regarded simply as secure sleeping places, where the birds are safe from attack by predators, but in winter Common Starlings also select warmer, less windy locations, including urban sites.*

[*Sturnus vulgaris vulgaris*, Rhineland-Palatinate, Germany. Photo: Manfred Pfefferle]

the control exhibited by the lack of collisions, have intrigued all observers who have witnessed them. Mathematicians have also puzzled over the spectacle, and their numerical models have indicated that such collective behaviour could emerge from simple local rules of interaction among the individual birds. Recently, a multi-author paper with a forbidding title, which does not mention starlings, proposed that the interaction in such flocks does not depend on the metric distance between birds, which had been the general working assumption, but, rather, on the topological distance between them. In practical terms, this implies that each bird, rather than monitoring all the birds within a given radius, keeps track of the current positions of six or seven individuals which are separated from it by a fixed number of other birds. The critical distance is thus topological, dependent on the structure of the surroundings, and not a simple linear measure of separation. Modelling of the process suggests that flocks organized on this principle are much more stable against perturbations, such as the attack of a predator, and are much less likely to split up and leave some individuals temporarily isolated and vulnerable. So, starlings can be as instructive in mathematics as they are in music (see Relationship with Man).

Most starlings seem to enjoy bathing in water, and some of the smaller species will also bathe in wet foliage. For Common Starlings, bathing is an important activity in pre-roost assemblies. All members of the family drink by sipping, raising the head to swallow, and Common Mynas have been recorded even as drinking hot seawater from pools in the upper tidal zone in the tropics.

Dust-bathing has not been reported for any sturnid species, but "anting", another activity possibly associated with plumage care, has been. Active anting, in which a bird picks up ants in the bill and "wipes" them through selected areas of the plumage, has been observed to be performed in the wild by three African and three Asian species, and there are records of anting by five African and eleven Asian sturnids in captivity. Passive anting, whereby a bird on the ground takes up a posture with wings spread, resembling the sun-bathing attitude, and allows ants to crawl through its plumage, is common among some corvids, such as the Eurasian Jay (*Garrulus glandarius*); this behaviour, however, has not hitherto been recorded for any starling species. The ants utilized are always members of the subfamily Formicinae, which release large amounts of formic acid when molested. There have been observations of starlings indulging in anting behaviour but using, instead, millipedes (Diplopoda), which produce volatile defensive secretions, and even of individuals employing other strong-smelling materials, such as mothballs. Since formic acid, when applied directly in the laboratory, is found to be toxic both to insects and to micro-organisms which may grow on the feathers, anting has often been regarded as a technique for ridding the plumage of ectoparasites. There is, however, no direct evidence that anting, as performed by the birds, does kill any ectoparasites, and in experimental studies it is striking that some individuals indulge in anting at every opportunity, whereas others do so seldom or never, and there is no apparent correlation with the extent of infestation with ectoparasites. This has led to speculation that birds may undertake this activity merely for sensory stimulation, and that it may represent behaviour akin to glue-sniffing or other forms of drug addiction among humans. Perhaps new techniques for recording the brain activity of anting birds will bring us closer to an answer to the question.

Preening forms an essential part of plumage maintenance, and all starlings spend part of their day in this activity. Allopreening, in which an individual grooms a partner of the same species, is an important element in the social behaviour of several species, and is usually directed at the head region. This behaviour is likely to be practised by starlings having long-term pair-bonds, and it has been noted for the Grosbeak Starling, the Black-winged Myna, the Bali Myna, the Black-collared Starling and the Red-winged Starling.

All starlings scratch by employing the indirect method, whereby they lower one wing and lift the leg on the corresponding side, and then reach over the wing in order to scratch the head. Starlings probably have good reason to scratch, as their nests are often infested with biting lice (Mallophaga) and mites (Acarina). In Africa, birds occasionally have ticks (Ixodoidea), sometimes engorged, on the head area; the starlings seem to be incidental hosts to these ticks, which are species normally affecting hares (*Lepus*) and other small ground-living mammals, rather than birds. Hippoboscid flies (Hippoboscidae), a dipteran family

the members of which have a flattened body and adhesive feet and which includes well-known agricultural pests such as sheep keds, can occasionally be seen as they scurry through the starling's feathers, particularly on the wings. Internal parasites include tapeworms (Cestoda) and roundworms (Nematoda); a recent report has attributed deaths of wild Wattled Starlings to the physical damage caused by the nematode *Diplotriaenia verminosis*. Starlings, as well as other birds, can be hosts to blood parasites, including avian malaria and West Nile Virus, both of which are transmitted by mosquitoes (Culicidae). At least in the United States, the introduced Common Starling seems to be a minor carrier of West Nile Virus, and does not itself suffer high mortality when infected.

Allofeeding, whereby birds feed members of the group which are neither their mates nor their offspring, is an unusual type of behaviour, and one which may serve to reinforce alliances between individuals. Observations of the African Pied Starling revealed that subadults were the most active age-class in allofeeding, but that food exchanges could occur between individuals of all ages, including the feeding of an adult by a juvenile. The genetic relatedness of the individuals was not known in this study, but most exchanges involved birds which had been helpers at the same nests in the previous breeding season. The donor appeared to have selected its chosen beneficiary in advance, and on finding a food item, typically a large insect, it would adopt a very upright posture and strut purposefully towards the other bird. Other African Pied Starlings which approached it en route were brushed aside until, finally, the recipient would crouch and receive the food. In a few cases in which the recipient did not respond appropriately, the donor would itself swallow the food. No other starling species have been reported allofeeding, but it may occur among some of the co-operative breeders which associate in groups throughout the year (see Breeding).

Voice

Starlings are not usually rated as great songsters compared with such bird families as the thrushes, whose voices seem more musical to the human ear. J. P. Chapin described groups of Splendid Glossy Starlings as gathering "to practise the most marvellous discords", and although many members of the family are highly vocal, they have received scant praise from the poets. A common feature of both African and Asian starlings is that they will gather in such groups, often termed "choirs" by the observers, and sing for extended periods. In Africa this is commonly in temporary aggregations during the hottest hours of the day, whereas some Asian species, such as the Common and White-vented Mynas (*Acridotheres javanicus*), are particularly vocal at their night-time roosts. Both sexes apparently participate, and in the case of the Common Starling song at the roost seems to play a role in the defence of favoured perches. It is not clear, however, what other functions such choruses may have in the social organization of the species concerned.

In common with many other bird species, male starlings sing in order to advertise their territories, both to females and to rival males, and to attract mates. These functions of song have been confirmed experimentally for the Common and Spotless Starlings, and can be expected to apply to many other sturnids. In cases when pair-members remain together for more than a single breeding season, specific calls would be expected to serve for communication between the partners; duetting has been reported for Brahminy Starlings and for Rüppell's Glossy Starlings. A field study of the vocalizations of the Red-winged Starling in South Africa has revealed interesting similarities to the Common Starling, both species having two main types of song, namely whistles and warbles. But there were also also striking differences, the Red-winged Starling's repertoire including notes used exclusively by males or by females but hardly any songs that are unique to a particular individual. These two species have very different social systems: the Red-winged Starling maintains a long-term pair-bond and the pair lives in an exclusive individual territory, whereas the Common Starling has a short-term pair-bond and a tendency towards colonial breeding.

For most species in the family, the full vocal repertoire has still to be described, and it is not possible to make any general statements about the ways in which the songs may be developed by young sturnids. Field and laboratory studies of the Common

Some members of Sturnidae are more aggressive than others. Among the mynas, ***Common Mynas*** *are notorious for their aggressiveness, both to one another, and to birds of other species. Fights may take place between individuals, or between groups. Following a chase, the birds may interlock their claws and peck at each other. In places where Common Mynas have been introduced, they tend to drive away less aggressive native hole-nesting species. Indeed, this species may have been responsible for driving the Rarotonga Starling* (Aplonis cinerascens) *from the lowlands of Rarotonga.*

[*Acridotheres tristis*, Berenty Reserve, Madagascar. Photo: Cyril Ruoso/Bios]

Preening forms an essential part of plumage maintenance, and all starlings spend part of their day in this activity. Mutual preening, or allopreening, in which an individual grooms a partner of the same species, is also an important element in the social behaviour of several species. Allopreening is usually directed at the head region, including the bare skin around the eye. Allopreening is usually considered evidence that pair-bonds in a species are likely to be long-term. It has been recorded in the ***Common Hill Myna****, which in the wild certainly pairs for several successive seasons, and may pair for life. It has also been noted in six other sturnids. A perhaps more unusual type of behaviour is allofeeding, whereby birds feed members of the group which are neither their mates nor their offspring. Allofeeding may serve to reinforce alliances between individuals. Observations of the African Pied Starling* (Lamprotornis bicolor) *revealed that subadults were the most active age-class in allofeeding, but that food exchanges could occur between individuals of all ages, including the feeding of an adult by a juvenile. Most exchanges in this study involved birds which had been helpers at the same nests in the previous breeding season. No other starling species has been reported allofeeding, but the phenomenon may occur among some of the co-operative breeders which associate in groups throughout the year.*

[*Gracula religiosa*. Photo: Luis Casiano]

*In stretching its wing, this **Red-cheeked Starling** is revealing its prominent white wingbar. Wing-stretching plays a small part in the time devoted to feather maintenance, and may simply be a way of easing tired muscles. Among different approaches to feather care, dust-bathing has not been reported for any sturnid species, but "anting" has been. Active anting, in which a bird picks up ants in the bill and "wipes" them through selected areas of the plumage, has been observed in the wild in three African and three Asian species, and in captivity in five African and eleven Asian sturnids. The ants used are always members of the subfamily Formicinae, which release large amounts of formic acid when molested. Since formic acid, when applied directly in the laboratory, is toxic both to insects and to micro-organisms which may grow on the feathers, anting has often been regarded as a technique for ridding the plumage of ectoparasites. There is, however, no direct evidence that anting kills ectoparasites, and in experimental studies it is striking that while some individuals indulge in anting at every opportunity, others seldom or never do so. There is also no apparent correlation with the extent of infestation with ectoparasites. This has led to speculation that birds may undertake this activity merely for sensory stimulation. There have been observations of starlings indulging in anting-style behaviour using, millipedes (Diplopoda), which produce volatile defensive secretions, and even of individuals employing strong-smelling materials such as mothballs.*

[*Agropsar philippensis*, Higashine, Yamagata-ken, Japan.

The feet are used to groom feathers which are beyond the reach of the bill, and also to remove ectoparasites. All starlings scratch the head in the way this ***Ashy Starling*** *is doing, by lowering one wing and lifting the leg over the wing to scratch. Starlings probably have good reason to scratch, as their nests are often infested with biting lice (Mallophaga) and mites (Acarina). In Africa, starlings occasionally have ticks (Ixodoidea), sometimes engorged, on the head area. The starlings seem to be incidental hosts to these ticks, which are species normally affecting hares* (Lepus) *and other small ground-living mammals. The Ashy Starling is confined to the interior of Tanzania, where it is common, and occurs in several national parks.*

[*Lamprotornis unicolor*, Tarangire National Park, Tanzania. Photo: Ketil Knudsen]

Starling make this one of the best-known of all bird species in terms of song acquisition and singing behaviour, and even the brain regions controlling particular aspects of vocalization have now been defined. Males continue to acquire new songs for at least eight years, and it seems that individual repertoires are restructured annually to some extent. Learning is dependent on a close association with the tutors, whether conspecifics or human care-givers, and male Common Starlings normally learn exclusively from other male starlings, whereas females acquire their song elements from other females. Females in the wild sing much less than males, and this appears to be influenced chiefly by sex hormones, but the social environment and the availability of nest sites are also important factors.

Vocal mimicry by birds remains a puzzling phenomenon, one for which there is no generally accepted functional explanation. Some starlings are highly accomplished mimics, incorporating into their repertoire the vocalizations of other birds and other animals, as well as human speech and whistles, and even artificial sounds such as those made by hammers, bells, machines, telephones and so on. Mimicry by the Common Starling has been studied in some detail, and similar patterns were found for individuals from Scotland, England, France, Germany and New Zealand. Certain species are imitated by Common Starlings much more frequently than are others, and this is not always a reflection of their abundance in the area, so that particular types of call or song are evidently favoured as models. Simple, pure calls are reproduced very accurately in whistling song, whereas the sounds imitated in warbling song are often modified and combined in complex sequences, with a great deal of individual variation. Imitations of the songs of other bird species have been reported also for the Shining Starling (*Aplonis metallica*), the Spotless Starling, the Brahminy Starling, the Common Myna, the Crested Myna (*Acridotheres cristatellus*), the Asian Pied Starling, and the Cape Glossy, Black-bellied Glossy and Splendid Glossy Starlings, as well as for the Amethyst Starling in captivity, while accurate imitation of the human voice is known to be accomplished by the Common Starling, the Common Myna, four hill mynas in the genus *Gracula*, and one African species, the Splendid Glossy Starling. The last-mentioned also reproduces the calls of monkeys. Mimicry could be a means of increasing the vocal repertoire of individual birds, but it may be merely a side effect of the extended learning period associated with the acquisition of complex songs.

Apart from songs, calls serve a very important function in communication. Flight calls are believed to contribute to the coordination of the movements of flock-members, while alarm calls are often mutually recognizable among species. In East Africa, Superb Starlings (*Lamprotornis superbus*), which forage mainly on the ground, have discrete alarm calls for aerial predators, snakes, and other ground-based predators. Vervet monkeys (*Cercophithecus aethiops*), which frequently feed alongside the starlings, recognize these different alarm calls and respond appropriately to them; young monkeys appear to learn the significance of the starling calls by observing the adults in the troop. Experimental studies of Common Mynas suggest that, while alarm calls associated with a potential predator are quickly learnt by naive birds, distress calls, such as those given by individuals held in the hand, are not necessarily associated with anti-predator responses. Vocal learning, even for apparently simple signals, may present unexpected subtleties for these starlings.

Food and Feeding

Starlings are generally categorized as frugivores or insectivores, yet some take a wide range of animal food up to the size of small vertebrates, as well as fruit and other vegetable material, so that they could be described, rather, as omnivores. There are clearly

Sunbathing may be part of the suite of feather maintenance activities. The warmth of the sun may make the feathers more flexible prior to preening, or may bring parasites to the surface where they can more easily be removed. This ***Hildebrandt's Starling*** *has fully spread the feathers of its wings and tail, and raised the feathers of its back and throat, enabling the warmth to penetrate. Some corvids, such as the Eurasian Jay* (Garrulus glandarius) *adopt the sunbathing posture while allowing ants to crawl through their feathers. But this behaviour, known as "passive anting", has not been recorded in any starling species.*

[*Lamprotornis hildebrandti*, Serengeti National Park, Tanzania.
Photo: Ketil Knudsen]

seasonal differences, too, in the diet, with a predominance of animal food during the breeding season. Many starling species will take nectar, in southern Africa particularly from the aloes (*Aloe*) which flower in winter, when other food may be scarce. Red-winged Starlings, African Pied Starlings and Cape Glossy Starlings are regular visitors to such aloe patches, and the introduced Common Starling is occasionally present, along with the Wattled Starling. On the dark plumage of most of these species, the bright orange pollen is highly conspicuous. The role of starlings in pollination of the aloes is unclear, but the brush-tipped tongue possessed by the Madagascan Starling and some Asian species, such as the Brahminy Starling (see Morphological Aspects), suggests that mutual adaptations between plants and their starling pollinators may have occurred. This possibility is reinforced by the frequency with which the crests of some *Acridotheres* mynas are covered with pollen when the birds are taking nectar from the flowers of such trees as *Bombax* and *Erythrina*. On the alpine moors of East Africa, where few other birds or insects venture, the Slender-billed Starling appears to be an important pollinator of the giant lobelias (Campanulaceae).

A wide range of cultivated and wild fruits is eaten by starlings, and studies in both Africa and Asia have confirmed that starlings are significant dispersal agents for several native tree species, such as the West African *Boscia senegalensis* and *Ster-*

For ***Common Starlings****, bathing is an important activity in pre-roost assemblies. They splash vigorously, plunging their heads under the water, flapping their wings and flinging the spray over themselves, until the feathers appear completely saturated and stand up in matted clumps. Bathing may be followed by a quick, cursory preen while the bird is still on the ground. Most starlings seem to enjoy bathing in water, and some of the smaller species will also bathe in wet foliage.*

[*Sturnus vulgaris vulgaris*, Hungary.
Photo: Markus Varesvuo]

Male starlings sing to advertise their territories and attract mates. These functions have been confirmed experimentally for the Common (Sturnus vulgaris) *and* ***Spotless Starling****. Male Spotless Starlings sing in most months, while both sexes sing in winter, and at the roost. The song consists of whistles and warbling phrases, with mimicry of at least 15 other species. The Spotless Starling song is similar to that of the Common Starling, which is one of the most studied bird species in terms of song acquisition. Male Common Starlings continue to acquire new songs for at least eight years, and normally learn from other males, while females learn from other females.*

[*Sturnus unicolor*, Puerto de Santa Cruz, Cáceres, Spain. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

culia quinqueloba in Malawi and, in Asia, the Indian banyan (*Ficus benghalensis*), white sandalwood (*Santalum album*) and neem (*Azadirachta indica*). The parasitic mistletoe *Phragmanthera dschallensis* in South Africa is bird-dispersed, with the Amethyst Starling one of its most effective distribution agents. A review of frugivory in the Oriental Region concluded that starlings of the genera *Aplonis*, *Acridotheres*, *Sturnia* and *Gracupica* are today probably the most abundant frugivorous vertebrates in many human-dominated landscapes, and thus play a crucial role in pollination and seed dispersal.

In South Africa, the native Red-winged Starling is considered an important disperser of the invasive Australian species *Acacia cyclops*, locally known as "*rooikrans*" because of the red (*rooi*) aril, attractive to the birds, which forms a wreath (*krans*) around the seed. Conversely, in Australia, the introduced Common Starling and Common Myna are important dispersal agents of the alien olive (*Olea europaea*) and, in the case of the Common Starling, olive stones may be transported over distances of up to 40 km. Observations of starlings feeding on over-ripe and fermenting fruit led to speculation that the birds might become intoxicated from the alcohol content. Laboratory experiments with Common Starlings demonstrated, however, that this species, at least, has at its disposal enzymes which break down alcohol very rapidly, so that even individuals provided with high concentra-

Despite its name, New Guinea's ***Singing Starling*** *is not a great songster, whether it be adult or, as here, immature. Its song is a short, melodious whistle. Other species make up in vigour and variety what they lack in tunefulness. Some gather in "choirs", and sing for extended periods. In Africa this is commonly during the hottest hours of the day, whereas some Asian species, such as the Common* (Acridotheres tristis) *and White-vented Mynas* (A. javanicus)*, are particularly vocal at their roosts.*

[*Aplonis cantoroides*, Port Moresby, SE New Guinea. Photo: Brian J. Coates]

*The song of the **Bristle-crowned Starling** is a complex of pure, musical whistles and warbling notes. Some starlings are highly accomplished mimics. Simple, pure calls are reproduced very accurately in whistling song, whereas the sounds imitated in warbling song are often modified and combined in complex sequences, with a great deal of individual variation. Non-bird sounds, such as the calls of monkeys, telephones and human speech, may be mimicked. There is no generally accepted functional explanation for mimicry. It could be a means of increasing the vocal repertoire of individual birds, but may just be a side effect of the extended learning period associated with the acquisition of complex songs.*

[*Onychognathus salvadorii*, Sof Omar, Ethiopia. Photo: Ketil Knudsen]

tions of ethyl alcohol in their diet showed no change in blood alcohol levels.

Anting, referred to earlier with regard to plumage care (see General Habits), has also been described as a technique for ridding these insects of the distasteful formic acid before consuming them. The Common Starling does eat ants, as well as anting enthusiastically, yet the two actions are not always associated, and there is little support for this explanation of anting behaviour. Other species, such as the African Pied Starling, may eat large numbers of ants but have never been observed to perform anting. Many starlings will hawk flying insects and termite alates (Isoptera); the latter, the winged reproductive termites which emerge during rainy periods, are a favourite bird food throughout Africa, eaten by almost any species. On the ground, starlings pursue other arthropods, including spiders (Araneae), sun-spiders (Solifugida) and centipedes (Chilopoda), and a few sturnids will feed on millipedes, which are often rejected as distasteful by both bird and mammal predators. Individuals foraging in the intertidal zone take worms (Annelida), snails and limpets (Mollusca), small crabs (Decapoda) and beach hoppers (Amphipoda).

Vertebrate prey include fish, which are caught in shallow pools, as well as small reptiles and amphibians, nestling birds, and probably also small rodents. Several ornithologists in Africa have noted that "bal-chatri traps", small cages festooned with nooses put out for raptors and shrikes (Laniidae) and baited with live mice (Muridae), immediately attract some of the larger starling species. Some sturnids, such as the African Pied Starling and Red-winged Starling, will also eat carrion, including vertebrates killed on roads, and meat on carcases at abattoirs.

Particularly when feeding young, Red-winged Starlings break up large prey items such as millipedes and solifugids by bashing them on stones, which serve as regular "anvil" sites. Similar behaviour has been reported for the Socotra Starling (*Onychognathus frater*) and Tristram's Starling (*Onychognathus tristramii*), and is quite likely to be employed by other species.

A few members of the family are known to puncture and eat the eggs of other birds. Indeed, both the Common Starling and the Common Myna are considered significant egg predators at seabird colonies on some oceanic islands. On the Azores, in the east Atlantic Ocean, where Common Starlings are responsible for significant egg losses at a Roseate Tern (*Sterna dougallii*) colony, quail (Phasianidae) eggs treated with methiocarb were deployed in a taste-aversion experiment. The starlings, however, then avoided quail eggs but continued to eat tern eggs, suggesting that a modified approach will be needed if the starlings are to be dissuaded from pursuing this diet. Both adults and nestlings of several species, including swifts (Apodidae), swallows (Hirundinidae) and members of the thrush family (Turdidae), have been attacked and killed by nesting Red-winged Starlings, but

*Starlings are generally categorized as frugivores or insectivores. But many, like the **Asian Pied Starling**, take such a wide variety of food types that they are perhaps better described as omnivores. Food can include fruit, flowers, nectar, seeds and cultivated cereal grains, and animal prey such as frogs, worms, snails, spiders and ticks, as well as insects of many kinds and sizes. The Asian Pied Starling forages primarily on the ground, in marshy grassland with scattered trees, often near cultivated areas and human habitation, or at sewage farms and rubbish dumps. It is usually found in pairs or in small parties of up to six individuals, although outside the breeding season, it may forage in larger groups of up to 30.*

[*Gracupica contra floweri*, Bangkok, Thailand. Photo: Tom Stephenson]

Although the two oxpecker (Buphagus) *species are now considered to lie outside the true starling lineage, a number of African and Asian starling species share the oxpecker habit of perching on wild mammals or livestock and removing ticks from them. This behaviour is particularly common among mynas. The* ***Great Myna*** *is so often seen perching on the water buffalo* (Bubalus) *that it has acquired the alternative name of "Buffalo Myna". Collared Mynas* (Acridotheres albocinctus) *are sometimes found in mixed flocks with Great Mynas around herds of livestock. In true oxpecker style, Bank Mynas* (A. ginginianus) *perch on cattle and remove ticks from them. As well as gleaning ectoparasites from their skins, Great Mynas use the large animals as beaters, and catch the insects they disturb as they move through the grass. Crested Mynas* (A. cristatellus) *also perch on the backs of buffaloes, from where they collect and hawk insects. Pale-bellied Mynas* (A. cinereus) *are usually found foraging on or around cattle, and Jungle Mynas* (A. fuscus) *similarly frequent grasslands grazed by cattle, and perch on their backs to hawk insects disturbed by them. In Africa, Greater Blue-eared Starlings* (Lamprotornis chalybaeus) *are often to be found perched on the backs of African buffaloes* (Syncerus caffer).

[*Acridotheres grandis*, N Thailand. Photo: Neil Bowman/FLPA]

Oxpecker-like behaviour is not only tolerated by many mammals, but apparently even welcomed by them, presumably because of the relief from discomfort which the removal of ectoparasites brings. In Israel, for example, both wild Nubian ibexes (Capra ibex) *and camels* (Camelus) *will visit regular sites, where they are systematically inspected by* ***Tristram's Starlings****. There is even an apparent mutual exchange of signals between the starlings and the ibexes. Tristram's Starlings are found in desolate rocky areas in deserts, and are apparently physiologically adapted to such conditions. They make opportunistic use of what resources are available, and have established themselves in towns, while those breeding outside urban areas may visit towns in order to forage, scavenging bread and dog food from houses. Tristram's Starlings have also been observed to pluck ticks from the hides of donkeys. The Red-winged Starling* (Onychognathus morio)*, Somali Starling* (O. blythii)*, Cape Glossy Starling* (Lamprotornis nitens) *and African Pied Starling* (L. bicolor) *have all been seen to remove ticks and other ectoparasites from domestic animals. Careful observation is necessary, however, because some birds use mammals simply as perches, from which they hawk insects, or drop down to the ground to catch insects disturbed by the passage of the mammals.*

[*Onychognathus tristramii*, Khawr Rawri, Oman. Photo: Hanne & Jens Eriksen]

Primarily insectivorous, ***Wattled Starlings*** *forage in association with wild and domestic ungulates. They perch on species such as Burchell's zebra* (Equus burchellii), *the white rhinoceros* (Ceratotherium simum), *and the blue wildebeest* (Connochaetes taurinus), *and may remove ectoparasites from them, and from sheep. Wattled Starlings also associate with African elephants* (Loxodonta africana), *but are displaced whenever they attempt to perch on them. Elephants have also been observed to reject the attentions of oxpeckers* (Buphagus), *suggesting that their skin may be more sensitive than might be expected. Meves's Long-tailed Starlings* (Lamprotornis mevesii) *follow moving elephants, catching insects disturbed by them.*

[*Creatophora cinerea*, Masai Mara National Park, Kenya. Photo: Michel & Christine Denis-Huot/Bios]

this appears to occur as an expression of interspecific territorial defence, rather than as predation.

Some birds are able to extract subterranean insects and worms from the grass mat by a specialized form of prying or open-bill probing, a method termed "*Zirkeln*" in the German literature, in which the closed bill is forced into the ground and then opened by specially strengthened jaw muscles. Within Sturnidae, this method of food-seeking is most highly developed in the Eurasian genera *Sturnus*, *Pastor* and *Agropsar* and some members of *Acridotheres*, *Poliopsar* and *Sturnia*, as well as in their African relative *Creatophora*. It has certainly preadapted these species for the exploitation of lawns, sports fields, and meadows closely grazed by domestic stock. A tame Common Starling often used this technique in order to open household objects such as matchboxes, and it would also try to force apart the fingers of its human keeper to gain access to hidden food.

Although the two oxpecker species, formerly treated as sturnids, are now considered to lie outside the true starling lineage (see Systematics), the oxpecker habit of perching on wild mammals and removing ticks from them has been reported also for several starling species in Africa and Asia. This behaviour is apparently tolerated by the mammals, which may even "welcome" it. In Israel, for example, both wild Nubian ibexes (*Capra ibex*) and camels (*Camelus*) will visit regular sites where they are systematically groomed by Tristram's Starlings. Similarly, in Africa, a small antelope of rocky hills, the klipspringer (*Oreotragus oreotragus*), appears to have a regular grooming relationship with Red-winged and Pale-winged Starlings, which are sympatric with the klipspringer in different parts of this antelope's range. The Great Myna (*Acridotheres grandis*), Common Myna, Jungle Myna (*Acridotheres fuscus*), Spotless Starling, Wattled Starling, Red-winged Starling, Somali Starling, Cape Glossy Starling and African Pied Starling have all been seen to remove ticks and other ectoparasites from domestic animals, and some probably feed in the same way from wild ungulates. Careful observation is necessary, however, as some birds clearly use mammals simply as perches, from which they hawk insects, or from which they drop to the ground to catch insects disturbed by the mammals.

Starlings which co-exist with humans have quickly learnt to exploit the food opportunities that people provide. Apart from their depredations in orchards and cropland, species such as the Common Starling may have a significant impact at feedlots for cattle. At picnic sites in game reserves in Africa, starlings of several species will gather for hand-outs. The Red-winged Starlings on the campus of University of Cape Town, in South Africa, do not merely check the radiator grilles of parked vehicles for trapped insects, but resident pairs routinely enter buildings to reach the student canteen and the dining halls, even where this entails that they follow passageways with only artificial lighting; the birds collect food items from unattended plates and then generally carry these outside to be eaten. After sunset, starlings will even hunt insects attracted to streetlights. Moreover, at some motorway service stations in the UK, Common Starlings have learnt that the front number plates and surrounding areas of cars provide an abundant source of freshly killed insects, especially in summer. This behaviour does seem to be specific to only a few of the country's many service stations, possibly indicating that it spreads through cultural transmission. Common Starlings feed frequently at sewage-treatment plants and refuse dumps, a habit which has led to some people becoming concerned about their potential for disease transmission.

Breeding

Starlings are often considered to be typically hole-nesting birds, utilizing natural tree holes and also cavities made by woodpeckers or barbets, as well as equivalent spaces in artificial structures such as walls and roofs and, in a few cases, tunnels excavated in the banks of rivers or dry gulleys. A number of sturnids, however, also build free-standing nests, which can be either domed constructions or open cup-nests. The nests may be scattered in individual territories, each occupied by a single pair, or they may be clustered in dense colonies. Some starlings exhibit a wide range of different nest-site choices, and also vary markedly with regard to their breeding densities in different situations.

Throughout the range of the family, most forest starlings are hole-nesters, although the Grosbeak Starling is the only member of the family with the ability to excavate its own nest-sites in timber. With its powerful bill and colonial habits, this species can weaken dead trees to the point at which they break; its nest has an entrance of about 4 cm in diameter, with a cavity extending downwards at an angle for up to 30 cm into the trunk. Another colonial forest-dweller is the Narrow-tailed Starling (*Poeoptera lugubris*), but it is dependent on colonial African barbets in the genus *Gymnobucco* for the provision of nest-sites. Surprisingly, several observers have reported that both the barbets and the starlings may be present at the nesting trees at the same time, and apparently share the facilities quite amicably. Whereas most of the African red-winged starlings in the genus *Onychognathus* nest in rocky areas, there is a short-tailed representative in montane forests, Waller's Starling (*Onychognathus walleri*), and a long-tailed relative in lowland rainforest, the Chestnut-winged Starling (*Onychognathus fulgidus*), both of which nest in tree holes within large territories, well separated from other nesting pairs.

Shining Starlings and Yellow-eyed Starlings (*Aplonis mystacea*) are both colonial forest birds, their nests usually concentrated in a single tree. These nests, of which there are often more than 100 at a single site, are globe-shaped structures suspended from the upper branches. Other *Aplonis* species nest mainly in tree holes, exceptions being the colonial White-eyed Starling, which builds tunnel-like nests among the epiphytes on branches in the canopy, and the Brown-winged Starling (*Aplonis grandis*), isolated pairs of which place a bulky nest in the fork of a tree or at the end of a broken branch. The nest-sites of a number of Asian forest starlings have apparently never been described.

Among the Asian starlings and mynas of more open country, a much broader interpretation of "nesting hole" is evident, and many species will use a wide range of both natural and artificial sites. Thus, Rose-coloured Starlings most frequently nest in the interstices between stones on scree slopes, but also use cracks in rocks, clefts in cliffs, holes in buildings, under roofs and in roof thatch, burrows constructed by Collared Sand Martins (*Riparia riparia*) and even holes in willow trees (*Salix*). More urbanized species, such as the Common Myna, nest in lampposts, air-conditioning vents, and abandoned vehicles and machinery. There is even a report of a pair of White-vented Mynas in Singapore which nested in a bus which was still in use for routine journeys. The habit of constructing tunnels in the soil is, however, restricted to a few species, notably the Bank Myna (*Acridotheres ginginianus*); rarely, Common Starlings, too, have been recorded as excavating their own holes in sand dunes. The nests of Asian Pied Starlings are domed and may be built on artificial structures, such as streetlamps, as well as in trees. They can be very bulky structures, dimensions of 60–80 cm across by 35–50 cm high having been recorded. Domed nests in trees, well protected by thorns, are the norm for several African species, such as the Superb Starling, the Chestnut-bellied Starling, Fischer's Starling (*Lamprotornis fischeri*), the White-crowned Starling and the Wattled Starling, the extensive colonies of which may include many nests clustered together in both indigenous thorn trees and exotic vegetation, including pine trees (*Pinus*) and gum trees (*Eucalyptus*).

The addition of mud to the nest structure, as opposed to the building of a nest entirely from mud, is an unusual technique among birds generally, and among the starlings it is restricted to some members of the genus *Onychognathus*, the African red-winged starlings, which build cup-nests on rocky ledges. All known nest-sites of the Slender-billed Starling have been in caves behind waterfalls with mud readily available, whereas the Pale-winged Starling, in the arid regions which it frequents, places its nests deep within rock clefts and does not use any mud. Most other Afrotropical starlings occupy tree holes, whether in forest or in savanna. Two species utilize tunnels in the soil. One of these, the Magpie Starling (*Speculipastor bicolor*), normally burrows into termite mounds, but it sometimes digs holes in riverbanks. The other, the African Pied Starling, can make its own tunnels in riverbanks and gulleys, but nowadays it often uses spaces in stone walls, gaps under the eaves of houses, and other opportunities presented by man-made structures.

Whether the nests are in holes or are free-standing, they may contain material from a variety of sources, including moss, grass, twigs, leaves, flowers, feathers, hair and wool, sloughed snakeskins, dung, wire, string, paper and plastics. Particular attention has been focused on the use of green leaves. These are often taken from aromatic plants, and it was proposed that they might serve as a natural insect-repellent agent, reducing the

In Namibia and South Africa, ***Pale-winged Starlings*** *regularly perch on klipspringers* (Oreotragus oreotragus) *and remove ectoparasites. The starlings are at least tolerated by the antelopes, and, in fact, appear to have a regular relationship with them. A similar relationship exists between the klipspringer and the Red-winged Starling* (Onychognathus morio), *which is sympatric with the antelope elsewhere in its range. Red-winged Starlings not only remove ticks, but may feed on secretions from the klipspringer's pre-orbital glands. The Pale-winged Starling also removes ticks from two species of mountain zebra* (Equus) *and from desert-dwelling giraffes* (Giraffa camelopardalis) *in Namibia.*

[*Onychognathus nabouroup*, Augrabies Falls National Park, South Africa. Photo: Oriol Alamany]

number of ectoparasites and thus improving the survival of the young. Most of the experimental work in this field has concentrated on the Common Starling. It seems clear that males of this species bring in green leaves during the courtship phase, before even eggs are present in the nest, and that the behaviour, therefore, represents a display directed at the female, rather than fumigation for the benefit of the nestlings. Leaves of certain plants are preferred, and there is evidence that male Common Starlings exhibit increased olfactory sensitivity during the breeding season, when fresh plant material is being brought to the nests. There seems, however, to be little convincing evidence that the presence of these leaves has any impact on the population of biting arthropods at a later date. Recent studies have raised the intriguing possibility that the young starlings might gain an unexpected advantage, since it appeared that, in nests with added aromatics, the chicks' immune systems were boosted, and the nestlings suffered less from insect bites and potential disease transmission. In the case of the Spotless Starling, the amount of green material contributed by the male seems also to advertise his quality as a mate. In turn, the female Spotless Starling brings in feathers and places them alongside the nest cup, such that they serve no purpose in insulation, but potentially provide a measure of her physical condition and experience. Fresh green leaves have been noted in the nests of several African starlings, but there are no experimental data which could perhaps indicate the functional significance of this behaviour for any of these species.

Confined nest-holes pose problems of space, and pollution from droppings and waste material from food, as well as ecto-

*These **Jungle Mynas** are using an Indian rhinoceros* (Rhinoceros unicornis) *to flush insects. India's Kaziranga National Park has the world's largest remaining population of these mammals, which are listed as Vulnerable by IUCN. When foraging on the ground, the Jungle Myna uses open-bill probing to collect insects in the grass. Jungle Mynas also feed on fruits and seeds, including cereals and groundnuts, and on the nectar of flowering trees, including* Erythrina, Bombax, Butea, Careya *and* Spathodea. *Pollen collects on its crest, and the myna is considered to be an important pollinator of these trees. Indeed, the frequency with which the crests of* Acridotheres *mynas become covered with pollen when they are feeding on nectar suggests that mutual adaptations between the birds and the trees may have occurred. Other nectar feeders among this genus include the Common Myna* (A. tristis), *which visits a similar range of flowering trees to the Jungle Myna. The Bank Myna* (A. ginginianus) *occasionally visits flowering* Erythrina *trees, while the Black-winged Myna* (A. melanopterus) *of Java and Bali may be predominantly a fruit and nectar feeder, spending much of its time in trees, although it also forages for insects on grassland and beaches.*

[*Acridotheres fuscus fuscus*, Kaziranga National Park, India. Photo: Bernard Van Elegem]

*The **Greater Blue-eared Starling** collects most of its food on the ground, where it hops, rather than walking or running like many terrestrial sturnids. Feeding mainly on fruit and insects, including locusts and other grasshoppers, beetles termites and ants, while captive birds also killed and ate frogs, lizards and baby mice. It hawks for flying insects, sometimes using large mammals as a perch, and forages in trees for fruit such as figs* (Ficus), *and nectar. It also feeds on the nectar of sisal* (Agave sisalana). *Greater Blue-eared Starlings have been observed taking ripe cereal grains, and also scavenging food discarded by people.*

[*Lamprotornis chalybaeus sycobius*,
Kruger National Park,
South Africa.
Photo: Rolf Kunz]

parasites, all of which are aggravated when the same nest-site is used repeatedly. Studies in the artificial environment of nestboxes provide some insight into these stresses, and it appears that, at least for the Common Starling, nestling survival rates are higher in more spacious nestboxes.

Eggs of exclusively hole-nesting species, such as barbets, and also of those building closed nests, such as waxbills, are pure white. The distinctively coloured eggs of many starlings have been cited as evidence that this family originated from birds which had open cup-nests, and that hole-nesting would therefore be a secondary adaptation and not the primitive condition for the family. Coloured eggs, especially with differences in coloration and pattern among individual females, have also been regarded as an adaptive response to brood parasitism by cuckoos (Cuculidae). The phenomenon of egg-matching, however, is demonstrated exclusively by those cuckoo species the young of which ejects the nest contents, so that the host invariably loses its entire clutch. Starlings appear to be parasitized chiefly by the Great Spotted Cuckoo (*Clamator glandarius*), which does not eject host eggs and young nor produce mimetic eggs. To date, parasitism by this cuckoo on starlings has been recorded only in Africa, where the Cape Glossy, Splendid Glossy and Rüppell's Glossy Starlings, Burchell's Starling (*Lamprotornis australis*), the Greater Blue-eared Starling, Meves's Long-tailed Starling, the African Pied Starling, Hildebrandt's Starling (*Lamprotornis hildebrandti*), the White-crowned, Red-winged and Pale-winged Starlings, and the introduced Common Myna have been documented as hosts. There are also a few West African records of parasitization by Levaillant's Cuckoo (*Clamator levaillantii*) on the Chestnut-bellied Starling; the eggs of the two species matched in background colour, but not in markings. In addition, some hole-nesting African starlings are victimized by other brood parasites: thus, the Cape Glossy and Greater Blue-eared Glossy Starlings are parasitized by the Greater Honeyguide (*Indicator indicator*) and the Amethyst Starling by the Lesser Honeyguide (*Indicator minor*), while the African Pied Starling is parasitized by both of those species. Although honeyguide chicks destroy their nestmates, the eggs of honeyguides are pure white; it may not, however, be feasible for the starlings to eject strange eggs from a deep nest-hole without damaging their own eggs in the process. African Pied Starlings are apparently able to usurp nest-sites of European Bee-eaters (*Merops apiaster*) by removing the latter's eggs from the nesting burrow, but they do this only prior to laying their own clutch. Perhaps the behaviour is "switched off" once the starlings have entered the egg-laying phase of the breeding cycle.

An alternative, and not mutually exclusive, explanation for the evolution of diversity in the egg patterns of individual females would be intraspecific brood parasitism. This is well documented for the Common Starling, and has been reported for several other sturnid species, such as the White-cheeked Starling, which will, incidentally, occasionally lay eggs also in the

*Termites are part of the diet of many ground-feeding sturnid species. Throughout Africa, starlings also hawk termite alates, the winged reproductive form which emerges during rainy periods. Although common within most parts of its range, and considered the commonest starling species in Uganda, no detailed information is available about the feeding preferences of **Rüppell's Glossy Starling**. It is described as almost omnivorous, its feeding grounds including camp-sites and picnic areas. A large glossy starling with a long, graduated tail, it forages predominantly on the ground, where it both hops and runs.*

[*Lamprotornis purpuroptera purpuroptera*,
Masai Mara National Park,
Kenya.

Ardea]

nests of the Purple-backed Starling. Starlings in these genera, however, do not lay patterned eggs, although their eggs do, nevertheless, display small variations in colour and shape. Furthermore, Common Starlings are known to be able to remove intact eggs from nests, and this habit is, in fact, a normal part of the nest-cleaning process by males following desertion of a clutch by a female.

Polygyny, whereby one male is simultaneously mated to more than one female, is recorded occasionally among starlings. In contrast to some other bird families, such as the weavers, however, there is no evidence that it is the regular mating system of any member of the Sturnidae. The two *Sturnus* species are opportunistically polygynous, mostly with only two mates, although up to five have been recorded in the field; less than 5% of the breeding males are involved in such behaviour. It is most often reported for the Common Starling, by far the best-studied species in the family. Polygyny by Common Starlings is generally an artefact of the provision of nestboxes, which enables a single male to defend and advertise more than one nest-site within a small area. Disturbance by human observers has also been cited as a contributing factor. In these situations, the male generally provides the primary, first-established female, but not the secondary female, with some assistance in the incubation of the eggs and the feeding of the young. It has been shown experimentally that the provision of additional nestboxes stimulates the male to display more, and thus to devote more attention to courtship than to parental care. A similar effect can be elicited, from starlings and some other species, by supplementary dosages of testosterone, which inhibits transition to the parental-care phase of the breeding cycle while keeping the male in mate-acquisition mode.

Although most starlings are likely to be socially monogamous, this need not imply long-term pair-bonds. Nevertheless, it is likely that, when partners stay together throughout the year, the pair-bond regularly lasts for several successive breeding seasons, and this has been confirmed for the Common Hill Myna, the Common Myna, the Red-winged Starling, the African Pied Starling and the Cape Glossy Starling. Genetic studies carried out as a means of determining the parentage of young birds have routinely revealed that species which appear, from behavioural observations, always to be monogamous may frequently indulge in extra-pair copulations, and this will doubtless prove to be the case for many starlings, too. Two studies involving DNA-fingerprinting of Common Starlings in colonies in Belgium and Sweden showed that, respectively, 9·7% and 8·7% of chicks were unrelated to the male of the pair which was rearing them. In the case of Spotless Starlings, under experimental treatments with hormones, up to 20% of chicks resulted from extra-pair fertilizations; importantly, these experiments showed that the number of chicks resulting from extra-pair fertilization was greater in nests of polygynous males than in nests of monogamous males, indicating a genetic cost of polygyny.

Although it is primarily a fruit eater, the ***Common Hill Myna*** *also includes insects and small vertebrates, such as lizards, as regular parts of its diet. Geckos (Gekkonidae) are taken from tree trunks, especially when the birds have young to feed. Many sturnid species which are fruit eaters for the rest of the year increase the proportion of animal food during the breeding season. Like the* Acridotheres *mynas, the Common Hill Myna frequently feeds on the nectar of flowering trees, its face becoming heavily dusted with pollen. Large numbers of Common Hill Mynas can gather at fruiting trees.*

[*Gracula religiosa andamanensis*, Havelock Island, Andaman Islands. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

The ***Micronesian Starling*** *regularly takes the eggs of seabirds, as it is about to demonstrate at this nest of a Black Noddy* (Anous minutus). *It may take advantage of some human disturbance at seabird colonies to attack eggs. Otherwise these birds forage in the understorey and canopy of trees, mainly eating fruit and seeds, as well as insects. Only a few members of the family are actully known to puncture and eat the eggs of other birds, but the Common Starling* (Sturnus vulgaris) *and the Common Myna* (Acridotheres tristis) *are considered significant egg predators at seabird colonies on some oceanic islands. In the Azores, Common Starlings are responsible for significant egg losses at a Roseate Tern* (Sterna dougallii) *colony.*

[*Aplonis opaca orii*, Palau Is. Photo: Mandy Etpison]

Observations of starlings feeding on over-ripe and fermenting fruit led to speculation that the birds might become intoxicated from the alcohol content. Laboratory experiments with ***Common Starlings*** *demonstrated, however, that this species has at its disposal enzymes which break down alcohol very rapidly, so that even individuals provided with high concentrations of ethyl alcohol in their diet showed no change in blood alcohol levels. Common Starlings are also able to eat the harmless aril of the yew* (Taxus baccata) *"berry", and defecate the seed, with its highly toxic coating. Yew berries are avoided by seed predators and other bird species which break seeds down in the process of digesting them.*

[*Sturnus vulgaris vulgaris*, Weesp, Netherlands. Photo: Will Leurs/ www.agami.nl]

In one study of the Superb Starling in Kenya, 14% of the offspring were fathered through extra-pair copulations. This is a socially monogamous species, which is also a co-operative breeder, and lives in groups of several potential breeders and helpers. Females can mate with group members or with "outsiders". Mating with several males within the group has the effect of recruiting additional helpers to feed the nestlings, whereas mating with other males offers only the potential genetic benefits of increased out-breeding and thus greater genetic variability in the offspring.

There is an interesting dichotomy between African and Asian starlings with regard to parental care. In the case of the African species for which data are available, either from field studies or from observations in captivity, only the female incubates, while the male sits nearby and sings. The only exception involves the Wattled Starling, which is Asian in origin, yet with all of the Asian starlings observed at the nest it was found that both sexes participate in the care of the eggs. Despite this, male starlings from both lineages help to feed the nestlings, and also feed the young after they have fledged. Both parents routinely remove faecal sacs from

The estimated proportions in the diet of the ***White-necked Myna*** *of Sulawesi are 78% fruit, 21% invertebrates, and less than 1% vertebrates. Found mostly in primary and secondary forest, it occurs more rarely in modified habitats, such as plantations. Studies in Africa and Asia have confirmed that starlings are significant dispersal agents for several native tree species, such as the West African* Boscia senegalensis *and* Sterculia quinqueloba *in Malawi and, in Asia, the Indian banyan* (Ficus benghalensis), *white sandalwood* (Santalum album) *and neem* (Azadirachta indica).

[*Streptocitta albicollis torquata*, Tangkoko-Dua Saudara Nature Reserve, N Sulawesi. Photo: Mark Jones/Roving Tortoise Photos]

Mulberries (Morus) *and other fruits are important to the* ***Rose-coloured Starling*** *in autumn and winter, but during the breeding season its diet is dominated by locusts and other grasshoppers. An individual bird can eat 120–220 locusts (particularly flightless hoppers) per day. Most locusts are taken on the ground, a group of birds hurrying in one direction, with those at the back of the flock flying over those in front, so that the group moves in a "roller-feeding" manner. Rose-coloured Starlings breed in large or very large colonies, on open steppes, where locusts and grasshoppers are abundant. Breeding is closely tied to food availability, and may be abandoned in a lean year for locusts.*

[*Pastor roseus*, Lesvos, Greece. Photo: Mathias Schäf]

the nest. Aggressive defence of the nest-site is a mark of certain pairs of Red-winged Starlings, which will swoop at passers-by and domestic animals, often approaching from behind and physically striking the intruder with their claws. In one intriguing example, a male of this species was caught and ringed at a nest-site on the campus of Rhodes University, in South Africa; the ornithologist, while leaving the building on the same evening, was attacked by the starling. On the following day, the ornithologist, in order to test the situation, walked out in the midst of a crowd of students, but he was immediately singled out for attack again. Clearly, some Red-winged Starlings can recognize individual humans, and one may perhaps be permitted to surmise, anthropomorphically, of course, that they can also bear personal grudges.

Co-operative breeding, or the phenomenon of helpers at the nest, whereby individuals other than the parents assist in the raising of the young, has been reported for many families of African and Asian birds. There are, however, only two known observations suggestive of occasional co-operative breeding by Asian starlings, these involving the Shining Starling and the Yellow-faced Myna. Among African starlings, co-operative breeding has

The ***Bronze-tailed Glossy Starling*** *is known to eat insects and fruits. It forages mostly on the ground, and less often in trees. There are second-hand reports of the birds scavenging at abattoirs. The Wattled Starling* (Creatophora cinerea) *scavenges at similar sites, and the African Pied Starling* (Lamprotornis bicolor) *and the Red-winged Starling* (Onychognathus morio) *have been recorded eating meat on carcasses at abattoirs, and carrion. The Bronze-tailed Glossy Starling is a poorly documented species, not always separable in the field from similar congeners like the Lesser Blue-eared Starling* (L. chloropterus)*, with which it often associates in mixed flocks.*

[*Lamprotornis chalcurus*, Western Division, Gambia. Photo: Dick Forsman]

Flocks of ***White-crowned Starlings*** *gather at fruiting* Salvadora *trees, and feed on cultivated dates* (Phoenix) *in Somalia. Feeding sturnids can cause damage to cultivated fruit, and several starlings and mynas are regarded as pests. However, a review of frugivory in the Oriental Region concluded that starlings of the genera* Aplonis, Acridotheres, Sturnia *and* Sturnus *are probably the most abundant frugivorous vertebrates in many of today's human-dominated landscapes, and thus play a crucial role in pollination and seed dispersal. Some have a less positive role, in that they disperse alien plants. In South Africa, for example, the native Red-winged Starling* (Onychognathus morio) *helps spread the invasive Australian* Acacia cyclops.

[*Lamprotornis albicapillus*, Ethiopia.
Photo: Jürgen Schneider]

been confirmed as regular or frequent for 15 species. All of the sturnids with helpers are resident birds of savanna, and there seems to be a clear association between co-operative breeding and highly seasonal and semi-arid environments. None of these species is sexually dimorphic, and all are mainly insectivorous or omnivorous, rather than primarily frugivorous; many of them breed colonially. On the basis of these criteria, it is likely that at least some other, poorly studied species may have helpers; species such as the Bronze-tailed Glossy Starling (*Lamprotornis chalcurus*), which has a wide distribution in seasonally dry savanna areas, should be investigated more closely. Three of the co-operatively breeding sturnids, namely the Superb Starling, the Chestnut-bellied Starling and the African Pied Starling, have now been studied in some detail in the field. In all cases, there is no involvement of individuals other than the parents during the nest-building and incubation stages, and, while some of the helpers are subadults and juveniles which are feeding younger siblings, unrelated birds do provide some additional assistance. Although there are a few records of group-members feeding the incubating female starling on the nest, this behaviour is apparently infrequent when

In Canada, the introduced population of ***Crested Mynas*** *eats cultivated and wild fruits such as cherry* (Prunus), *mountain ash* (Sorbus), Rubus *berries, and currants* (Ribes). *Fruit makes up 60% of the diet in Canada but in the Crested Myna's native southern China, the proportions are 55% animal food, and 45% vegetable matter. Crested Mynas are usually found in open country, including cultivated land, where they forage by probing the grass for ant and cranefly (Tipulidae) larvae, or by hawking for flying insects. They will also scavenge dead fish, and one was seen to harass a nestling Chinese Pond-heron* (Ardeola bacchus) *until it regurgitated its food.*

[*Acridotheres cristatellus cristatellus*, China.
Photo: Zhao Chao]

*A gregarious species with a typical sturnid diet of fruit, nectar and insects, the **White-headed Starling** forages in trees and shrubs. It sometimes joins mixed flocks of foraging insectivores which include drongos (Dicruridae), and cuckoo-shrikes and minivets (Campephagidae). Starlings are not often recorded in mixed-species flocks of insectivorous birds, although a few species do so on a relatively regular basis.*

[*Sturnia erythropygia andamanensis*, Andaman Islands. Photo: Konrad Wothe]

compared with similar behaviour by other co-operative breeders such as the babblers (Timaliidae) and the bee-eaters (Meropidae).

The conflicts and benefits to individual birds in co-operative breeding systems are of great interest, and new genetic and physiological techniques now enable studies to be undertaken on these aspects. For the Superb Starling in Kenya, Rubenstein showed that females may use extra-pair copulations with flock-members as a means of recruiting additional helpers, as described in the preceding paragraphs. More surprising is the finding that the sex ratio of nestlings varies in different seasons according to maternal body condition: in good years more female offspring are produced, and in poor years more males are produced. Where dominance plays a major role in determining breeding status, heavy females are more likely to become future breeders. There is a complex interaction among environment, hormone levels and social behaviour; in bad years, poor food supplies reduce body condition, and while high hormone levels can ensure high rank and thus access to food, elevated levels of steroid hormones also have a negative impact on the physical condition of the bird, and the time spent in social competition reduces foraging time. It has

*The highly opportunistic and almost omnivorous **Red-winged Starling** takes nectar from a wide range of plant species. Stone "anvils" are used to break up hard-shelled prey such as millipedes and sun-spiders (or solifugids). Red-winged Starlings exploit human modification of the environment in many ways, for example hawking insects by artificial light after dark. Perhaps applying the techniques used to glean ectoparasites from large animals, they visit car parks to glean insects from radiator grilles. At the University of Cape Town, South Africa, resident pairs enter buildings and traverse corridors to collect food from unattended plates.*

[*Onychognathus morio morio*, Cape Point, Western Cape, South Africa. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

All members of the family drink by sipping, raising the head to swallow. The ***Common Starling*** *also visits water margins for prey which can include small frogs and toads. Like its congener, the Spotless Starling* (Sturnus unicolor), *it is highly adapted for open-bill probing to extract invertebrates from the sub-surface of grassland. In both* Sturnus *species, and in the White-cheeked Starling* (Poliopsar cineraceus), *which is also highly adapted for open-bill probing, the protractor muscles are very strongly developed, the skull is greatly narrowed, and the eye can be moved forwards to peer down along the line of the bill.*

[*Sturnus vulgaris*, Alicante, Spain. Photo: Markus Varesvuo]

been suggested that social interactions in such societies drive the relative costs of being dominant, or breeding, and of being subordinate, or non-breeding, and that behaviour is the main influence on stress hormone levels. With the Superb Starling, however, it appears that environmental conditions influence the costs of dominance and of subordination, which in turn affect the intensity of social interactions between the birds, and ultimately determine their roles in the breeding system. In the Kenya study, the number and proportion of first-time breeders was higher in seasons following wetter years than in those following dry years. Variable environments are thus responsible for many of the variations in the breeding patterns and success of some bird species.

Movements

Bird-ringing as a technique for studying migratory movements, using unique identification numbers for individual birds, began in 1899 when a Danish schoolmaster, Hans Christian Mortensen, started to ring Common Starlings in his village in an attempt to discover their whereabouts in the winter. The northern populations of the Common Starling are, indeed, migratory, with north–south movements typical of populations breeding in the eastern part of the species' range, these spending the non-breeding season in western China and northern India, Pakistan, Afghanistan and the Middle East. In western Europe, the direction

The habitat of the ***Greater Blue-eared Starling*** *is dry savanna woodland, which in West Africa extends into desert zone. But like other sturnid species, it needs access to standing water for drinking and bathing, and the West African birds apparently move south in the dry season. Availability of water may limit distribution. For example, the Madagascan Starling* (Hartlaubius auratus) *is found throughout the coastal areas of Madagascar, except in the arid south-west corner. The movements of other sturnids of arid areas, such as the Magpie Starling* (Speculipastor bicolor), *may also be related to seasonal availability of water.*

[*Lamprotornis chalybaeus cyaniventris*, Ethiopia. Photo: I. R. Beames/Ardea]

Common Mynas (Acridotheres tristis) *have been recorded drinking hot seawater from pools in the upper tidal zone in the tropics. But the* ***Yellow-faced Myna****, found in wet forest habitats of different kinds, including rainforest and swamp-forest, has easy access to fresh water. It is primarily a frugivore. Despite its large size, the Yellow-faced Myna also hawks insects from high branches. Usually seen in pairs, it is also found in small groups, and occasionally in larger mixed-species flocks of frugivores. It is often found feeding in the company of another of the mynas of the New Guinea region, the Golden Myna* (Mino anais).

[*Mino dumontii*, near Brown River, SE New Guinea. Photo: Brian J. Coates]

of migration is to the south-west or even the west of the breeding areas, Scandinavian breeders typically moving west-south-west for the winter. The wintering areas of these birds embrace the western seaboard of Europe southwards to the Iberian Peninsula and to African countries north of the Sahara, individuals sometimes reaching the Atlantic islands of the Canaries, Madeira and the Azores. Juveniles from Switzerland initially move north-west to the North Sea and Atlantic seaboard prior to their autumn migration southwards.

The introduced Common Starling population in North America is also migratory in the northern part of its range. Although there is no recognized regular migration in Australia, long-distance movements of Common Starlings have occasionally been recorded. Moreover, individuals of this species sometimes manage to cross from South Australia into Western Australia, traversing the inhospitable terrain of the Nullarbor Plain.

True migration by birds implies discrete breeding and non-breeding areas which are occupied at different times of the year, the migrants generally following a clearly defined route when moving between the two areas. By these criteria, there are few other starling species which can be categorized as migrants on the basis of current knowledge of their movements. In the Indian Subcontinent, the Spot-winged Starling breeds in the western Himalayas and then migrates eastwards to Assam; it is often as-

During courtship, the song of the male ***Common Starling*** *is often accompanied by a peculiar rotation of the half-open wings around the shoulder joint. The elongated feathers of the throat and upper breast are erected during the display. By the breeding season, the pale tips of the feathers have become abraded, particularly on the breast, exposing a strong purple gloss on the head and throat, and a green gloss on the mantle, rump and breast. Male Common Starlings bring green, often aromatic, leaves to the nest during courtship and before egg-laying, which is thought to be an offering directed at the female. The males exhibit increased olfactory sensitivity during the breeding season.*

[*Sturnus vulgaris vulgaris*, Goor, Netherlands. Photo: H. Bouwmeester/ www.agami.nl]

Most forest starlings are hole-nesters. The ***Coleto*** *of the Philippines is found in lowland forests, and in coconut groves, where it nests in holes in dead trees, or in the rotting trunks of coconut palms. A distinctive grey-and-black sturnid, with bare skin covering most of its head, except for a narrow central line of bristly black feathers, it is apparently monogamous. Most hole-nesting forest starling species make use either of natural cavities, or of holes excavated by birds such as woodpeckers (Picidae) and barbets (Capitonidae). The Narrow-tailed Starling* (Poeoptera lugubris)*, a colonial forest-dweller, is dependent on colonial African barbets in the genus* Gymnobucco *for the provision of nest-sites. Surprisingly, several observers have reported that the barbets and starlings may be present at the nesting trees at the same time, and apparently share the facilities quite amicably. The Common Hill Myna* (Gracula religiosa) *may also nest in association with other species, such as the Vernal Hanging-parrot* (Loriculus vernalis)*. Its nest-holes tend to be at least ten metres above the ground. Common Hill Myna nest-holes may be reused in subsequent years. But confined nest-holes pose problems of space, and pollution from droppings and waste material from food, as well as ectoparasites, and all of these are aggravated when the same nest-site is used repeatedly. Studies in the artificial environment of nestboxes suggest that, at least for the Common Starling* (Sturnus vulgaris)*, nestling survival rates are higher in more spacious cavities.*

[*Sarcops calvus melanonotus*, NW Panay Peninsula, Panay, Philippines. Photo: Tim Laman/ naturepl.com]

Closely associated with human-modified habitats, some ***Bank Mynas*** *make use of sites such as brick kilns, bridges and similar structures for their nest-holes. Otherwise, they generally excavate their own nest tunnels in banks of rivers. The tunnels are up to a metre long and end in a broader chamber, which is lined with straw, feathers, pieces of sloughed snakeskin, polythene and other material. In captivity, birds added fresh green leaves regularly. Other urban-adapted species, such as the Common Myna* (Acridotheres tristis)*, nest in lampposts, air-conditioning vents, and abandoned vehicles and machinery. There is a report of a pair of White-vented Mynas* (A. javanicus) *in Singapore which nested in a bus which was still in use.*

[*Acridotheres ginginianus*, Varanasi, Uttar Pradesh, India. Photo: Bernard Castelein/ naturepl.com]

sociated with the Chestnut-tailed Starling, some populations of which migrate. Although the Rose-coloured Starling is nomadic within its breeding range, which extends from eastern Europe east to Central Asia, this species has a regular migration to the Indian Subcontinent, where it is a non-breeding visitor with a clearly defined wintering range. In the latter region, some populations of the Brahminy Starling are migratory within India. Farther east, from north-east India east to the Philippines, the Sundas and Sulawesi, Asian Glossy Starlings are regarded as local migrants which leave the breeding areas each year. Similarly, the Shining Starlings which breed in Queensland, north-east Australia, are seasonal visitors from New Guinea. In China, the White-cheeked Starling, the White-shouldered Starling and the Purple-backed Starling all migrate from northern breeding grounds to non-breeding areas farther south on the Asian mainland, while the Red-cheeked Starling migrates from central Japan and more northerly islands southwards to wintering areas primarily in the Philippines and Borneo.

In the Afrotropics, the various populations of Amethyst Starlings all appear to carry out migrations between breeding and non-breeding areas, with the picture complicated by the fact that a given region may be occupied successively by different populations of breeding and non-breeding birds. From the base of the Horn of Africa, Amethyst Starlings fly across the Red Sea to the Arabian Peninsula, where they are breeding migrants in south-western Saudi Arabia, Yemen and Oman. On the southern fringe of the central African forests, the Splendid Glossy Starling is apparently a migrant, making seasonal visits to its breeding areas in Angola, Zambia and East Africa; elsewhere, its movements are not so clearly defined. Regular migration seems to be the best explanation for the pattern of seasonal occurrence of two East African species, the Magpie Starling and Hildebrandt's Starling, their movements being apparently related to regional rainfall patterns.

Many other sturnids display less predictable movements, which appear to be linked to the seasonal distribution of food supplies. Frugivorous species may temporarily concentrate in flocks at fruiting trees. For example, large numbers of Black-bellied Glossy Starlings appear at the western limits of the species' range in the coastal belt of South Africa during winters when the tree *Rapanea melanophloeos* produces an abundance of fruits. Red-winged Starlings form large mobile flocks in the non-breeding season, and in one year individuals of this species ringed on Rhodes University campus, in South Africa, were recovered a few weeks later on the coast, 40 km due south, and also at inland sites 100 km to the north and 50 km to the north-west. The largely insectivorous Wattled Starling is truly nomadic in the African savannas, with breeding regionally unpredictable and opportunistic in association with temporarily abundant insect food, such as locusts (Acrididae) at the hopper stage or the noctuid-moth caterpillar known as the "karoo rusper" (*Loxostege frustalis*). In recent years, its wanderings have taken flocks to Madagascar and Aldabra, and stragglers have appeared even in the Seychelles, about 1500 km from the East African coast, but the Wattled Starling which landed on a fishing vessel 100 km west of South Africa would not have reached South America unassisted.

A similarly nomadic lifestyle likewise dependent on the patchy occurrence of superabundant insects, primarily locusts, is pursued by the Rose-coloured Starling in Central Asia. This species makes occasional irruptive movements far to the west of its usual breeding range, and migrants at times also overshoot to the east, with, for example, several records in Thailand. More recently, there have been three records of Rose-coloured Starlings in sub-Saharan Africa.

Relationship with Man

The earliest interactions between humans and starlings were undoubtedly those of predator and prey. Archaeological work on Pacific islands has revealed that the first Polynesian settlers had a dramatic impact on island faunas, and precipitated many extinctions. Starlings are well represented in the bones retrieved from these sites, and even today Asian Glossy Starlings and Micronesian Starlings (*Aplonis opaca*) are captured and eaten regularly by some islanders. In northern India, similarly, adult Common Hill Mynas are still trapped for food. The commonest local starling species no doubt formed an item in the diet of numerous people throughout Asia and Africa. In Europe, too, sturnids have been exploited as food. In the Netherlands, Com-

*Alone among forest starlings, the **Grosbeak Starling** is able to use its massive bill to excavate its own nest-holes in rotten trees in the manner of a woodpecker. Also like woodpeckers, Grosbeak Starlings have jaw muscles greatly enlarged to protect the brain from concussion. A highly gregarious species, the Grosbeak Starling lives in flocks of up to 150 individuals. Collectively, colonially nesting Grosbeak Starlings can weaken dead trees to the point where they collapse. The nest has an entrance about 30–40 mm in diameter, with a cavity extending downwards at an angle for up to 30 cm into the trunk. Both males and females line the cavity with grass and leaves. Captive pairs used green leaves in courtship and nest-building. Two eggs are laid, but wild pairs apparently produce only one young per nest. Nest-holes are apparently used throughout the year for roosting. Grosbeak Starlings are generally found at forest edge and in lightly wooded areas. Common in modified habitats, and most frequently encountered in plantations, they are relatively uncommon in primary forest, and evidently absent from secondary forest.*

[*Scissirostrum dubium*, Lore Lindu National Park, Sulawesi.
Photo: Pete Morris]

mon Starlings were encouraged to nest in clay pots and the young were harvested, a practice that extended from the fourteenth century up to as recently as the nineteenth century. Common Starlings are still captured for food in parts of southern Europe, and tinned starling pâté, *pâté de sansonnet*, was widely available in southern France in the late 1980s.

Markets in Africa still include large sections devoted to traditional health remedies, and to materials used in preparations purported to have magical properties. Dead animals and animal parts are an important element at these stalls, and surveys have highlighted the presence of many endangered species among the animals offered for sale. Starlings, however, are generally not a significant component. Of 7000 birds identified at a market in Benin, only 31 were starlings; the sturnids involved were Neumann's Starling, the Chestnut-winged Starling, the Purple Glossy Starling (*Lamprotornis purpureus*) and the Splendid Glossy Starling, all relatively common species in this region. Economic factors, however, seem to play an important role, with greater reliance on traditional medicines when pharmaceutical products become more expensive, whereas the vendors report reduced demand if cheaper generic medicines are readily available.

Urban roosts of Common Starlings in the British Isles were first recorded in the 1840s, but initially the birds always roosted in trees. Once the trees lost their leaves, the birds began to move on to buildings. The starlings achieved national notoriety on 12th August 1949, when a pre-roost assembly perched on the hands of London's famous clock, "Big Ben", in such numbers that their combined weight stopped the clock. This led to questions being asked in parliament, and even calls for the extermination of the Common Starling. Perhaps the greatest accolade for this species following these events was, however, the devotion of an entire episode of the cult 1950s radio programme, *The Goon Show*, to London's starlings and how to get rid of them. Roosts in cities have caused concern in view of the quantity of droppings deposited by the birds overnight. These faeces are malodorous, are unsightly, and can damage masonry and the paintwork of cars. They also render walkways and roads dangerously slippery, and in some regions serve as foci of infection for the fungus *Histoplasma capsulatum*, which can cause serious pulmonary disease in humans. In Asian cities such as Singapore, Common and White-vented Mynas are a nuisance primarily because of the noise emanating from their roosts; Asian Glossy Starlings and Purple-backed Starlings which share these sites are much quieter birds. Dissuading starlings from using roost-sites which people find inappropriate has, however, proved very difficult.

Birds which inhabit open grassland are naturally attracted to airfields, and in these situations they can be involved in collisions with aircraft. Such events, known as "bird strikes", are monitored at all airports, but starlings, because of their small body size and the current standards of aircraft engine, designed to cope with bird impacts, do not rate as a major problem. Nevertheless, a dense flock of starlings presents a real hazard. For example, in

Sturnid nests may be scattered in individual territories, each occupied by a single pair, or they may be clustered in dense colonies. The Australasian ***Shining Starling*** *is one of the colonial breeders, with four to 400 nests in a colony, often built in a single tree. While starlings are often considered to be typically hole-nesting birds, a number also build free-standing nests, which can be either domed constructions, or open cup-nests. Shining Starlings build domed nests with side entrances, made from twigs, vine tendrils and bark strips, lined with strips of palm frond and fresh green leaves, and suspended 10–30 m above ground from the ends of twigs. Adjoining nests can coalesce to form a single structure. Apparently there may be up to three successive broods at the same colony, but it is not clear if the same individual birds are involved. Although the species is assumed to be monogamous, it is possible that Shining Starlings may be co-operative breeders at times, with three or more adults working on one nest. The clutch is of one to four eggs. Incubation may be performed by the female alone, but the chicks are fed by both sexes, by regurgitation and with food carried in the bill. There is a constant loud twittering at colonies, and returning individuals give a high-pitched twittering call. Primarily resident or nomadic, the Shining Starling is largely a breeding visitor in north-east Australia, spending the non-breeding season in New Guinea. In New Guinea, some colonies are treated as a traditional food source by humans, with certain individual people having the right to harvest nestlings. In Australia, likewise, the young were formerly collected for food by Aboriginals. But this species features less in the trade in wild birds than do other members of its genus.*

[*Aplonis metallica metallica*, Mission Beach, Queensland, Australia. Photo: Marie Read]

Compared to forest-dwelling starlings, Asian starlings and mynas of more open country use a much wider range of natural and artificial nest-holes. Breeding colonies of ***Rose-coloured Starlings*** *often consist of hundreds, thousands and occasionally tens of thousands of nests. The season is very short, and the nest is built rapidly, by both sexes. Made from grasses and twigs, it is lined with finer grasses and feathers, and may include aromatic plants. Nests are most frequently placed between stones on scree slopes, but sometimes in cracks in rocks or cliffs, among stones on railway embankments or quarries, or in crevices in buildings. Occasionally the holes of Collared Sand Martins* (Riparia riparia) *are used, and even holes in trees.*

[*Pastor roseus*, Mt Ararat, Turkey. Photo: Hanne & Jens Eriksen]

October 1960, at Boston, in the north-east United States, 62 people were killed when a Lockheed Electra aeroplane crashed at Logan International Airport after a collision with Common Starlings, and the same species was responsible for the crash of a Lockheed C-130 military transport aircraft at Eindhoven, in the Netherlands, in 1996 which killed 34 people. In February 1999, again in the United States, a Boeing 757 lost an engine after taking in 400 Common Starlings during take-off, and was forced to make an emergency landing at Cincinnati, in Ohio. At some military airfields, falconers have been employed successfully to clear birds from the aircraft flightpath, and at some airports dogs of the border collie breed have been used to chase off birds; in both cases, the use of real potential predators ensures that, in contrast to what is generally the case with most mechanical or auditory scaring devices, the birds do not become habituated and consequently ignore the disturbance. Most "bird-scaring", however, is now undertaken in a somewhat more sophisticated manner, whereby starling distress calls are broadcast at flocks as these appear on the airfield or at nearby roosts, but appropriate management of the grassland, often by maintaining a particular grass height, is arguably the most potent means of making the area permanently less attractive to birds.

In an agricultural context, starlings can be beneficial or damaging. Pliny the Elder described the Rose-coloured Starling as a destroyer of locusts, and the Wattled Starling also has been labelled as a locust bird (see Movements). Both species can form vast flocks, which may have some local impact on the numbers of the insects. Studies on the possible use of biological methods to control insect pests in India suggested that, on balance, the Brahminy Starling, the Asian Pied Myna, the Jungle Myna and the Bank Myna were beneficial in terms of the harmful insects which they consumed, whereas the Common Myna ate seeds as well as insects, thus reducing success both at sowing time and during the harvest. Foresters in Korea were encouraged to put up nestboxes for Purple-backed Starlings, which consumed many insect pests, and in the former Soviet Union nestboxes were put up for Common Starlings, which were considered beneficial to both forestry and agriculture. On the other hand, a critical study of the Common Starling in New Zealand, where the species has been introduced, concluded that only with exceptional coincidences of high sheep grazing pressure, high rainfall and high starling density was any meaningful control achieved of local concentrations of the scarabaeid grass grub beetle (*Costelytra zealandica*). Unfortunately, some introductions of the Common Myna on oceanic islands were claimed to be justified on the basis that the birds would control insect pests; this would seem to be at best debatable, and the results of these introductions were usually undesirable. Apart from their "usefulness" in eating harmful insects, starlings could be beneficial to agriculture, and to the wider environment, through their pollination of flowers or their dispersal of seeds of plants of economic or biodiversity importance, but there is currently only anecdotal evidence for their role in these activities.

Damage caused by starlings has received much more attention. Soft fruit, especially grapes (*Vitis*), dates (*Phoenix*), mulberries (*Morus*) and cherries (*Prunus*), are targeted by many species. These include the African Pied Starling, the Wattled Starling, the Pale-winged Starling and the Red-winged Starling in southern Africa; the Greater Blue-eared Starling and the Superb Starling in Tanzania; the Common Starling in Britain, France, Spain, north Africa, New Zealand and the United States; the Spotless Starling in Spain and north Africa; the Bank Myna, the Jungle Myna, the Common Myna and the Rose-coloured Starling in India; the White-cheeked Starling in Japan; and the Samoan Starling (*Aplonis atrifusca*) in Samoa. Cereal crops are damaged by Greater Blue-eared Starlings in Chad, by Superb Starlings in Tanzania, by Bank Mynas and Common Mynas in India, and by Common Starlings in Europe and the United States. The Common Starling has been the focus of major control operations in these last two regions, but, although huge numbers of starlings were killed, there was little evidence of an overall reduction in the population or in the damage that they cause. Currently, the Common Starling is declining in many European countries, but this appears to be related to large-scale agricultural changes, rather than being due to the impact of control measures (see Status and Conservation).

Avian influenza and the associated scaremongering in the early years of the twenty-first century highlighted the possible role of birds as vectors of infectious diseases dangerous to humans. Starlings were not implicated as carriers or victims of the

*This **White-cheeked Starling** has caught food to take back to the nest. Although monogamous, this species is sometimes guilty of both interspecies and intraspecies brood parasitism. It nests in colonies of up to 30 pairs, and the first clutches are highly synchronous. Clutches can consist of two to ten eggs; this varies annually, and declines during the course of the season. Intraspecific brood parasitism was recorded in 18–24% of nests in one study. No eggs are removed when the parasite female adds an egg to the clutch. Late breeders appear to be responsible for most parasitism, behaving as floaters during the early part of the breeding season. Occasionally female White-cheeked Starlings also lay eggs in the nests of Purple-backed Starlings* (Agropsar sturninus). *Intraspecific brood parasitism has also been recorded in Common Starlings* (Sturnus vulgaris). *This may be the explanation for the evolution of diversity in the egg patterns of individual female sturnids. Coloured eggs, especially with differences in coloration and pattern among individual females, have also been regarded as an adaptive response to brood parasitism by cuckoos (Cuculidae). Egg-matching, however, is demonstrated exclusively by cuckoo species whose young eject the nest contents, so that the host invariably loses its entire clutch. Starlings appear to be parasitized chiefly by the Great Spotted Cuckoo* (Clamator glandarius), *which does not eject host eggs and young, nor produce mimetic eggs. The eggs of hole-nesting species are usually pure white, and the distinctively coloured eggs of many starlings have been cited as evidence that this family originated from birds which had open cup-nests, and that hole-nesting is a secondary adaptation and not the primitive condition for the family.*

[*Poliopsar cineraceus*, Beijing, China. Photo: Yilun Qiao]

*Co-operative breeding has been confirmed as regular or frequent for 15 African starling species, including the **African Pied Starling**. Up to five helpers, primarily subadult and unpaired individuals, have been recorded at the nests of this species, which are usually in tunnels up to 1·8 m deep, excavated by the birds themselves in riverbanks or similar sites. All the sturnids with helpers are resident birds of savanna, and there seems to be a clear association between co-operative breeding and highly seasonal and semi-arid environments. None of these species is sexually dimorphic, and many of them breed colonially.*

[*Lamprotornis bicolor*, Nieuwoudtville, Namaqualand, Northern Cape, South Africa. Photo: Peter Steyn/Ardea]

H5N1 strains of avian influenza, but experimental tests in West Africa showed that ground-feeding birds such as the Long-tailed Glossy Starling could potentially serve as intermediate hosts of the tick-borne Crimean–Congo haemorrhagic fever virus. Under natural conditions, however, wild and domestic mammals remain the primary reservoir hosts for this disease.

Humans have affected starling populations most directly through deliberate and accidental introductions. Four species, the Common Starling, the Common Myna, the Crested Myna and the Common Hill Myna, have been introduced, and have become well established, in regions beyond the natural range of the family. Of these four, the Crested Myna has been the least successful. This species continued to occupy a small area around the point of introduction in British Columbia, in south-west Canada, until the early years of the twenty-first century, when it was reported as extirpated in North America, whereas a population first reported in Argentina in 1982 appears to be expanding. This may be related to the temperature tolerance range of this essentially tropical species. The Common Hill Myna has established small populations, probably originating from escaped cagebirds, in the southern US state of Florida, in Puerto Rico and in the Hawaiian Islands. Both Common Starlings and Common Mynas have been

*Although both sexes of the **White-cheeked Starling** incubate the eggs, the female does most of the work. Incubation lasts 12–13 days. The chicks are fed by both parents, and the nestling period is 21–22 days. The White-cheeked Starling is an Asian species, and there is an interesting dichotomy between African and Asian starlings with regard to incubation and care of the eggs. In the African species for which data are available, only the female incubates. The only exception is the Wattled Starling* (Creatophora cinerea), *which is recognized as a species of Asian origin. Male starlings of both African and Asian lineages help feed the nestlings and the young after fledging.*

[*Poliopsar cineraceus*, Kahoku-cho, Yamagata-ken, Japan. Photo: Hirozo Maki]

The addition of mud to the nest structure, as opposed to the building of a nest entirely from mud, is an unusual technique among birds generally, and among the starlings it is restricted to some members of the genus Onychognathus, *which build cup-nests on rocky ledges. The* ***Amethyst Starling*** *of the monotypic genus* Cinnyricinclus, *however, commonly lines its nest with dung; donkey, horse and elephant dung have all been recorded. As in other starlings of the African lineage, incubation is carried out by the female alone, over a period of twelve to 14 days, but the chicks are fed by both parents. There is one record of two males and one female feeding chicks, but no evidence that co-operative breeding is a regular occurrence. Genetic studies to determine the parentage of young birds of other families have routinely revealed that species which appear, from behavioural observations, always to be monogamous, may frequently indulge in extra-pair copulations. This will doubtless prove to be the case for many starlings, too. Two studies involving DNA-fingerprinting of Common Starlings* (Sturnus vulgaris) *in colonies in Belgium and Sweden showed that, respectively, 9·7% and 8·7% of chicks were unrelated to the male of the pair which was rearing them. Studies of Spotless Starlings* (S. unicolor) *showed that the number of chicks resulting from extra-pair fertilization was greater in nests of polygynous males than in nests of monogamous males, indicating a genetic cost of polygyny—or that what is sauce for the gander can also be sauce for the goose.*

[*Cinnyricinclus leucogaster verreauxi*, KwaZulu-Natal, South Africa. Photo: Guy Upfold]

*The nestlings of the **Chestnut-tailed Starling** are fed mainly with insects, particularly caterpillars and beetles. Both males and females incubate the eggs and feed the chicks. There is no information on incubation and nestling periods for this, or for two other members of this genus. However, in the Brahminy Starling* (Sturnia pagodarum), *where the male is reported to feed the female on the nest, incubation lasts 12 days, and the nestling period 18–21 days. Hatching success was 91–95% over four years, and overall nesting success 67%. The species of this genus are highly arboreal, but on non-breeding grounds the White-shouldered Starling* (S. sinensis) *has been seen to forage on the ground among cattle.*

[*Sturnia malabarica*, Assam, India.

introduced in South Africa, Australia and New Zealand, and in all three areas Common Starlings appear to be the more widespread and abundant species. Range expansion of both species continues in southern Africa, and Common Mynas have recently colonized Swaziland and Botswana. From an initial release of 99 Common Starlings in New York, there are now, according to some estimates, more than 300 million individuals of this species in the United States and Canada combined, so that the colonization of North America has been an unqualified success for this bird; in this region, it is not confined to the proximity of human settlements. In South Africa, in contrast, the Common Starling is an urban bird, and in rural areas it is found only in the immediate vicinity of buildings. A more recent development, and a worrying one, has been the appearance and subsequent establishment of Common Starlings in Buenos Aires, in Argentina. Continued expansion by this species could take it outside urban habitats and into the vast wet grasslands of the *pampas*, a habitat that looks, at least superficially, to be eminently suitable for it. Here, it could interact both with agriculture and with native bird species.

On a worldwide basis, the Common Starling has been included among the 100 most invasive species, and it has been a "key witness" in several studies in which the reasons why some introduced alien organisms are highly successful in new habitats whereas others fail have been examined. Since, for several starling introductions, the numbers of individuals introduced in the first instance are known, genetic and morphological changes in the species concerned could provide clues as to how quickly populations adapt to new environments. Thus, for both the Common Starling and the Common Myna, data on New Zealand individuals 100 years after their introductions there suggested that the phenomenon of genetic drift in small isolated populations had occurred, resulting in random, non-adaptive changes. In contrast, the rapid spread of the introduced Common Starling in North America and its large population there today have led to very low genetic diversity among widely separated populations. The Common Myna has been introduced in Singapore, Hong Kong, Brunei, Sumatra, the Caucasus, Saudi Arabia, the United Arab Emirates and Iraq, and also on many islands. These are, in the Atlantic Ocean, Ascension, St Helena and, in the Canary Islands, Tenerife; in the Indian Ocean, Madagascar, the Comoros, the Mascarenes, the Seychelles, the Agalega Islands, the Chagos Islands, the Laccadives, the Maldives, and the Andamans and Nicobars; and, in the Pacific Ocean, Taiwan, Hawaii, the Solomons, Vanuatu, New Caledonia, Fiji, American Samoa, Western Samoa, and islands in the Cook, Society, Tuamotu and Marquesas Groups. Whereas most introduced populations are restricted to settlements, those on the oceanic islands are widespread in open or wooded habitats outside natural forests. Other sturnid species which have been introduced at new localities within the natural distribution of the starling family are the Jun-

***Kenrick's Starling** is a restricted-range species of the Tanzania-Malawi mountains Endemic Bird Area. A poorly known species, it may form a superspecies with Stuhlmann's Starling* (Poeoptera stuhlmanni) *and has been considered conspecific with it. There is little information about the breeding biology of either species. Kenrick's Starling has been recorded breeding in January, March to May, June to July and September to November, although the main season appears to be October. The third member of the genus, the Narrow-tailed Starling* (P. lugubris), *is a colonial breeder. Only females at colonies have been seen with bent tails, suggesting incubation is by the female alone.*

[*Poeoptera kenricki*, Arusha National Park, Tanzania.
Photo: Anabel Harries]

Like many others in the genus Aplonis, *the* ***Asian Glossy Starling*** *is sometimes a colonial breeder. As well as using tree-holes, it sometimes builds its rough, cup-shaped nest of roots, grass and leaves in the crowns of palm trees. It may also build among epiphytes in large trees. The White-eyed Starling* (A. brunneicapillus) *of the Solomon Islands also nests among epiphytes on branches in the canopy. Colonies of 10–40 nests are built in isolated trees. The sympatric Brown-winged Starling* (A. grandis) *is a solitary nester, which builds a free-standing bulky mass of twigs, dry leaves, moss and grass, with a side entrance, in the fork of a tree, or a cavity at the end of a broken branch.*

[*Aplonis panayensis strigata*, Singapore. Photo: Ong Kiem Sian]

gle Myna, in Fiji and Samoa; the White-vented Myna, in Sumatra; Singapore and Puerto Rico; and the Crested Myna, in Singapore, the Philippines and Japan.

In addition to the Common Myna, nine species of exotic starling have been recorded in Taiwan, but it is not clear how many of them have self-sustaining breeding populations. The ritual release of captive birds, practised by both Buddhist and Taoist believers as a meritorious activity, may be promoting the spread of alien bird species in Taiwan, although this is a speculative association at present. In a survey conducted in 1996, it was estimated that, of 68,538 "prayer birds" offered for sale, 6% were non-indigenous in Taiwan, the most common species being the Common Myna, the White-vented Myna and the Jungle Myna. Common Hill Mynas and Black-collared Starlings are also commonly sold in pet shops in Taiwan, and even Asian Glossy Starlings have been offered for sale in a few shops.

A major concern with introduced starlings has been the perception that they will outcompete and displace native species. A

As an almost cosmopolitan species, thanks to introductions, the ***Common Starling*** *suffers the attentions of a wide variety of nest predators, from squirrels (Sciuridae), stoats* (Mustela erminea) *and black rats* (Rattus rattus), *to the Little Owl* (Athene noctua), *and, as here, the European Roller* (Coracias garrulus). *Nevertheless, hatching success is high, at more than 70%. Fledging success is more variable, at 29–98% in different studies, with inter-annual variation, and second broods often less successful than first ones. A long-term study in southern England found large annual differences in the percentage of young returning to the colony, suggesting inter-annual differences in survival or emigration. Few second-brood chicks returned.*

[*Sturnus vulgaris vulgaris*, Hungary. Photo: Markus Varesvuo]

*The nestling period in the **Common Starling** is 21 days. In this and the closely related Spotless Starling* (Sturnus unicolor), *both parents feed the chicks and remove faecal sacs, although in both species the female does a larger share of the work. When male Common Starlings are polygynous, one or more females are often left to raise the brood unaided. Polygyny in Common Starlings is generally the result of the provision of nestboxes, which enables a single male to defend and advertise more than one nest-site within a small area. This stimulates the male to devote more attention to display and courtship than to parental care. Conversely, shortage of nest-sites can lead to fighting.*

[*Sturnus vulgaris vulgaris*, near Ringwood, Hampshire, England. Photo: Mike Read]

key factor in the success of these exotic species, however, has always proved to be their ability to associate closely with people, and to tolerate greatly modified habitats and high levels of disturbance, to which they are better suited than the indigenous birds which they have replaced. They generally do not penetrate undisturbed natural habitats. In Singapore, Common Mynas prefer agricultural areas, and they have apparently declined as such areas have been converted to housing, whereas White-vented Mynas evidently prefer greenery in the built-up suburbs. The five exotic sturnids recorded as now breeding in Japan are the Common, Bank, Jungle and Crested Mynas and the Asian Pied Starling; all are closely associated with human habitation. In garden habitats, both Common Starlings and Common Mynas are aggressive birds, often dominating and physically displacing other species in order to gain access to food, water and nesting sites. There are numerous anecdotal accounts in the literature of Common Starlings being seen to drive away woodpeckers and other species, often in suburban gardens.

In North America, where Common Starlings do enter natural habitats, there were reports that this species was displacing native hole-nesting birds from nest-sites, and starlings were implicated in the national decline of such species as the Eastern Bluebird (*Sialia sialis*). A recent review of long-term population data for this bluebird and 26 other hole-nesters in the United States concluded, however, that the arrival of Common Starlings did not have a significantly negative effect on the population density of the native species except, possibly, in the case of the sapsuckers (*Sphyrapicus*), which are relatively small woodpeckers no bigger than the starling itself. Interestingly, a British survey of Great Spotted Woodpecker (*Dendrocopos major*) numbers during the population decline of the Common Starling concluded that high starling numbers had previously reduced the woodpeckers' breeding success, but it was also noted that a continued increase in woodpecker numbers, long after starling interference had ceased to be important, would have to be attributed to other factors.

Introduced Common Mynas have been implicated in the declines of two island endemics. On St Helena, the myna is apparently a predator on the nests of the St Helena Plover (*Charadrius sanctaehelenae*), a Critically Endangered species, although cat predation and habitat change seem to be major factors in the plover's population decline. There is more direct evidence of nest destruction and interference by Common Mynas in the case of the Seychelles Magpie-robin (*Copsychus sechellarum*), and a myna-control programme forms part of the current recovery plan for this Endangered species. Attempts to eradicate mynas have now been made on several islands in the Seychelles, but hitherto none has been entirely successful. Nevertheless, there is now an active campaign to eradicate the Common Myna and other mynas from islands around the world, but all such efforts will require considerable funding, as well as major dedication and persistence with the control operations.

The commitment needed for a determined effort to eradicate introduced starlings is demonstrated by an ongoing programme with Common Starlings in Western Australia. These birds were successfully introduced into south-eastern parts of Australia in the 1800s, but they failed to reach Western Australia, probably because the arid Nullarbor Plain presented an impenetrable barrier. In the 1970s, however, a few hundred individuals were recorded in the south of the state. By this time, the potential adverse environmental and economic effects of Common Starlings were being recognized both in Australia and in other parts of the world, both in their natural range and in regions where they had been introduced. The Western Australian government wished, therefore, to avoid such problems and established a control programme, which successfully eradicated these early incursions; moreover, it maintained surveillance and, where necessary, control for the following 30 years. In the earliest years of the twenty-first century, however, a new incursion was discovered to be larger than had at first been perceived, and eradication attempts appeared not to be producing the required results. Using population data and damage estimates from other parts of the world, an economic study suggested that, if eradication failed and the starlings spread to the more fertile and agriculturally productive west of the state, the cost of damage that could follow over the long term warranted substantial immediate expenditure to undertake research on the Common Starling's biology in its southern habitats and on improved control measures, along with continuation of existing practices of shooting birds at their nests and trapping them wherever and whenever possible. A total of more than two million Australian dollars has been devoted to this eradication attempt, involving more than 20 permanent and temporary staff and employing specialist advisers from abroad, in order to continue the effort and to improve the control methods. Demographically, this project is a fascinating one. In 2006, the immigrant starling popu-

*During the nestling period of 22–27 days, young **Common Mynas** are fed by both parents, which continue to feed them for several weeks after they leave the nest. Hatching of the 4–5 eggs is often asynchronous, and brood reduction may occur. Hatching success in India is 90%, and in Thailand 73%. Fledging success for natural populations in Asia is 54–76% of eggs laid, with first broods more successful (75%) than second broods (60%), or third broods (under 40%). Solitary nesters, Common Mynas pair for successive seasons, and perhaps for life. Long-term pair-bonds have also been confirmed for the Common Hill Myna* (Gracula religiosa), *and three African species.*

[*Acridotheres tristis tristis*, India. Photo: Gertrud & Helmut Denzau]

Chicks of the co-operatively-breeding ***Superb Starling*** *are fed by both parents and by helpers for 4–7 weeks after leaving the nest. The majority of helpers are male offspring from previous broods. Despite this assistance, breeding success is low. Over four years in Kenya, 75% of nests failed, 90% of the losses being due to predation. In another study in Kenya, 14% of offspring were fathered through extra-pair copulations. Extra-pair mating within the "home" flock has the effect of recruiting additional helpers to feed the nestlings.*

[*Lamprotornis superbus*, Kenya. Photo: Kim Taylor/ naturepl.com]

lation was estimated to be around 2000 individuals, but these were distributed over about 1000 km²; in practice, what is being attempted is the eradication of a rare bird. The Western Australian Department of Agriculture is aware of the problems which this presents, but at this point it is prepared to invest sufficient commitment and funding to maximize the possibility of achieving success.

Greek and Roman literature indicates that Common Starlings were kept as cagebirds more than 2000 years ago, because of their ability to imitate human speech. Laboratory studies have confirmed that this species can imitate both spoken phrases and whistles used regularly by its caretakers, and that these sounds are easily recognized by other listeners. Common Starlings, however, tend to modify such acquired sounds to introduce "off-key" elements. The composer Mozart had a pet starling, and he wrote down a phrase which the bird whistled regularly; some other musical fragments among his music compositions seem to bear the characteristics of Common Starling song. Rather surprisingly, Common Starlings have even attracted the attention of some current popular musicians. In 1972, the guitarist and singer Eric

The ***Red-billed Starling*** *is thought to be resident or a partial migrant in most of its range. It is a non-breeding visitor to Vietnam and Hong Kong between November and March, the birds involved probably migrants from the north of the breeding range. Formerly a vagrant in Japan, it is now an annual visitor, and it also seems to have become fairly regular, if scarce, in Taiwan, where this photo was taken. Perched beneath the two males and above the two females is another winter visitor to the island, a* ***White-shouldered Starling****.*

Island endemics are always at particular risk, and the five species of starling known to have become extinct in the past three centuries were all found on oceanic islands. Although not globally threatened, and in fact widely distributed and common on many of the islands in its range, the ***Polynesian Starling*** *is nevertheless a restricted-range species. Its twelve recognized subspecies are distributed among the Vanuatu, Temotu, Fiji and Samoan Islands Endemic Bird Areas, and the Rotuma, Wallis and Futuna, Niuafo'ou, Tonga and Niue Secondary Areas. Another restricted-range species, the* ***Socotra Starling****, is found on Socotra, an island EBA in the Indian Ocean. Its population was estimated at 12,000 individuals in 2003. The Socotra Starling was formerly rated as Vulnerable, but it is now regarded as not globally threatened. However, the situation of island endemics can change with catastrophic speed. Now Critically Endangered, the Pohnpei Starling* (Aplonis pelzelni)*, found only on the island of Pohnpei in the Caroline Islands, appeared to be reasonably common in 1930. But the species was not found at all during a survey in 1983, and it was thought to be extinct, until a specimen was obtained in 1995. Habitat loss, hunting and predation by rats may account for its decline. Another Caroline Island endemic, the Kosrae Starling* (A. corvina)*, was extinct by 1931. Ironically, given that habitat destruction is often the main driver of the extinction of forest-dwelling species, the forests of Kosrae were, and still are, largely intact. The extinction of Kosrae's two endemic birds was probably due to predation by rats.*

*A distinctive myna with a wispy crest, white lower back, long graduated tail and a large patch of bare yellow skin around the eye, the **Apo Myna** is a restricted-range species, endemic to Mindanao, in the Philippines. Although very localized, it is common within suitable habitat, above 1250 m in forest and forest edge. Because such sites are rugged and inaccessible, they are considered to be secure, although some logging and clearance has taken place at lower elevations. The bird has been recorded in cut-over areas, but studies are needed into its tolerance of secondary habitats, and its response to fragmentation. As its range is so small and fragmented, any increase in the rate of human intrusion could have a significant negative effect, and the Apo Myna is considered Near-threatened.*

[*Basilornis mirandus*, Mount Kitanglad National Park, Mindanao, Philippines. Photo: Jon Hornbuckle]

Clapton mentioned "tired starlings" in his song *White Room*, while in 1978 the pop group Dire Straits, in the song *Lions*, refers to the flying antics of starlings at their roosts, seemingly a reference to the Common Starlings which at that time roosted nightly in central London.

Coletos in the Philippines are kept as pets because they are said to mimic human speech, and Common and Crested Mynas can also be taught to utter a few phrases, but the best "talkers" are reputed to be the hill mynas. In India, young Common Hill Mynas are taken both from artificial nest-sites and from natural holes in trees, whereas adult Southern Hill Mynas are captured by trappers in southern India. Sri Lanka Hill Mynas are also popular cagebirds, and many of them are taken as young from the nests. Reports from India and Thailand suggest that, in each country, more than 20,000 hill mynas are sold annually as cagebirds on the open market. The robbing of natural nests is now threatening the survival of Common Hill Mynas in Thailand, and, although this species is currently seldom bred in captivity, trials suggest that this could be a practical method of reducing the pressure on the wild populations. Indonesia, too, has a long tradition of bird-keeping, and a survey revealed that 22% of households in five major cities kept pet birds, in many cases wild-caught species, which included starlings. Novel vocal characteristics were sought after, and in 1998 hill mynas which could sing the soccer World Cup theme song fetched three to four times the normal price.

Brahminy Starlings are esteemed songsters in India, and are often kept for this reason. The Bali Myna was regarded as a status symbol for affluent and influential people in Java and Bali, and this was the primary cause of its popularity as a cagebird in the region. The striking plumage of many starlings, coupled with the attraction of exotic birds for affluent bird-fanciers, has led to a great variety of species appearing in the bird trade, and finding their way both to private collections and to zoological gardens and, for some species, thence into the wild.

Although at least 26 different members of the Sturnidae have been bred in aviaries by dedicated aviculturalists and specialist zoos, most captive birds are wild-caught individuals, and high mortality occurs in transit. Records from Delhi airport, in India, for the years 1983–1990 showed that, in every year, more than 3000 "mynas", a designation which could represent nine different starling species, were exported legally. Clearly, these official records from a single export site represent only a very small proportion of the true numbers of starlings traded, and they emphasize that customs officers are generally ill-equipped to identify the species involved.

In addition to the Greek and Roman literature already mentioned, more recent writings have cited Common Starlings, occasionally with unexpected ramifications. For example, Shakespeare's reference to the starling's ability to talk was to result ultimately in the species' introduction in North America. A wealthy American of German descent, Eugene Shieffelin, led one of many acclimatization societies in the United States in the second half of the nineteenth century. It is claimed that Shieffelin intended to introduce all of the birds mentioned by Shakespeare, and he did, indeed, import many, most of which failed to become established. His greatest success, however, was with the Common Starling, which he imported from England and released into Central Park, New York, in 1890. This species is now one of North America's most numerous, and probably most damaging, birds.

Status and Conservation

Island endemics are always especially at risk, and the five species of Sturnidae known to have become extinct in the past three centuries were all found on oceanic islands (see HBW7, pp. 54–55). One of these is the Norfolk Island Starling (*Aplonis fusca*), including the Lord Howe subspecies *hulliana*, the latter sometimes thought to have been a separate species, the "Lord Howe Starling"; both populations were extirpated in the early decades of the twentieth century. The others are the Mysterious Starling (*Aplonis marvornata*), from Mauke, in the southern Cook Islands, the

*There are few recent records of the **Emerald Starling**, which has a limited distribution in savanna woodland in three West African countries. Non-breeding flocks of up to 50 birds have been recorded in Sierra Leone. In 2001, flocks of up to 100 birds were seen at Mt Sangbé National Park, in Ivory Coast, and in 2002 a single bird plus a flock of ten were seen at two sites in the Pic de Fon Forest Reserve, Guinea. Because of the lack of information about its populations, the Emerald Starling is listed as Data-deficient. From 1981 to 1984 large numbers, probably from Guinea, were kept by bird traders in Monrovia, Liberia, and offered at a relatively low price per pair. The birds can be bred in captivity.*

[*Lamprotornis iris.* Photo: Rob Curtis/ The Early Birder]

Kosrae Starling (*Aplonis corvina*), from Kosrae, in the Caroline Islands, the Reunion Starling, from Reunion, in the Mascarene Islands, and the Rodrigues Starling (*Necropsar rodericanus*), from Rodrigues, also in the Mascarene Islands. The last is known only from skeletal material, whereas all of the others, including both subspecies of the Norfolk Island Starling, are represented by museum skins.

On Norfolk Island, the English explorer Captain J. Cook reported no sign of human settlement, but after a British penal colony was established there, in 1788, evidence of earlier Polynesian inhabitants was discovered. The Norfolk Island Starling survived these first settlers, but disappeared after European settlement, presumably under hunting pressure from the new colonists and nest predation by their accompanying animals; it was last recorded around 1923. Lord Howe Island, 1000 km north-east of the south-east Australian city of Sydney, was evidently first visited by humans in 1788, but it was not regularly inhabited until the 1840s. In 1913–1915, "Lord Howe Starlings" were re-

*The majority of the eight globally threatened and nine Near-threatened sturnid species are from islands around southern Asia and the Pacific Ocean. Only two African species feature on the list: the Vulnerable **Abbott's Starling** and the Near-threatened Copper-tailed Glossy Starling* (Hylopsar cupreocauda). *Abbott's Starling is found in a few montane-forest localities in Kenya and northern Tanzania. Little of its highland forest habitat is adequately protected, and recent surveys suggest that it is restricted to forest sections with the least human disturbance. There is some evidence of falling populations at sites where it was formerly categorized as common, such as Mt Kilimanjaro (Tanzania), and the Kikuyu Escarpment (Kenya).*

[*Pholia femoralis*, Mount Meru, Tanzania. Photo: Martin Goodey]

Several Aplonis *starlings have become extinct or exceedingly rare for reasons that are unknown, so careful monitoring is needed. The* ***Rarotonga Starling****, a shy and inconspicuous inhabitant of undisturbed montane forest in the interior of Rarotonga in the Cook Islands, was regarded as abundant in the nineteenth century. In 1973 the population was still put at several thousands, but by 1984 there were estimated to be no more than 100 left. More recently, this figure has been revised to around 500. The disappearance of this species from the lowlands may have been due to competition from the Common Myna* (Acridotheres tristis)*, but this introduced species is thought not to have penetrated the forested uplands.*

[*Aplonis cinerascens*, Rarotonga I. Photo: Pete Morris]

ported as present in thousands, damaging crops, especially fruit, and eating the eggs of other birds. Rats, however, were accidentally introduced from a grounded ship in 1918, and within a few years the starling was apparently extinct.

The Mysterious Starling is, indeed, a mysterious taxon, known only from a single specimen collected in 1825 while it was hopping about in a tree. No further birds were collected from the island of Mauke for almost 150 years, by which time the species had disappeared. Nothing is known of its biology and ecology, nor are there any clues to the reasons for its extinction. The large Kosrae Starling was first discovered in 1827 by the German ornithologist F. H. von Kittlitz, at the time attached to a Russian expedition. It was restricted to the high forests of the interior of Kosrae, and may still have been present in 1880 when F. H. O. Finsch visited the island, since Finsch did not collect in the forests. By 1931, however, it had disappeared, as a museum expedition searched the interior thoroughly but without success. There was still intact forest, but rats were present, and they may have played a role in the disappearance of this species, as well as being responsible for the demise of the Lord Howe taxon.

On Reunion, the local starling was reported as common in 1800, feeding on berries and also, probably, on nectar, as the tongue has a distinctive frayed tip (see Morphological Aspects). Live individuals were captured in 1835, yet in 1837 apparently the last specimen was shot. There are specimens of the Reunion Starling in several museums, including some preserved in alcohol, which have been dissected by anatomists in the twentieth century, and this species was included in a recent molecular phylogeny of the family (see Systematics). The species sported a crest, a trait which is today restricted to some Asian starlings such as those in the genera *Acridotheres* and *Basilornis*.

Known only from skeletal material, the Rodrigues Starling was apparently seen by a French visitor around 1726. The extinct *Aplonis diluvialis* from Huahine, in the Society Islands, was described from bones at an archaeological site dated at 1250–750 years before the present. As a final point of interest, recent studies, using both morphology and DNA data, have revealed that the specimen of a second supposed extinct starling from Rodrigues, named *Necropsar leguati*, is not a starling at all; it is, in fact, an albino trembler (Mimidae) from the West Indies which had been incorrectly labelled.

Of the 112 extant species in the Sturnidae, eight are globally threatened. Of these, two are listed as Critically Endangered. These are the Bali Myna and the Pohnpei Starling (*Aplonis pelzelni*). The decline in numbers of the Bali Myna is well documented. The population numbered 200 individuals in the early 1980s, but it has not risen above 50 since then. This species' original range on Bali has contracted as a result of habitat destruction, with woodland converted to coconut and kapok plantations, and human settlement. The main threat, however, has been the capturing of the starlings for the local cagebird trade. The wild population is currently estimated at 24 individuals, mostly released as part of a recovery programme; globally, more than 1000 are held in captivity. Until the Bali Myna's security within the Bali Barat National Park can be guaranteed, there would seem to be little prospect of re-establishing a wild population of this species. Fortunately, this is considered one of only two starling species which breed readily enough in captivity to supply the cagebird trade in Europe and North America.

The Pohnpei Starling, found only on the island of Pohnpei, in the Caroline Islands, appeared to be reasonably common in 1930. Nevertheless, during a survey undertaken about half a century later, in 1983, the species was not found. This starling was thought to be extinct, until a specimen was obtained in 1995. Habitat loss, hunting by the human population on the island, and possible predation by rats may account for the decline of this sturnid.

Two species, the White-eyed Starling of the Solomon Islands and the Black-winged Myna of Java, Bali and Lombok, are Endangered. The four remaining globally threatened sturnids are listed as Vulnerable: they are the Mountain Starling (*Aplonis santovestris*), confined to one island in Vanuatu, the Rarotonga Starling (*Aplonis cinerascens*), restricted to Rarotonga, in the Cook Islands, the White-faced Starling, found only in Sri Lanka, and Abbott's Starling (*Pholia femoralis*), restricted to a few mountains in East Africa.

A further nine species are currently listed as Near-threatened. These are the Rusty-winged Starling (*Aplonis zelandica*), of the Santa Cruz Islands and Vanuatu; the Tanimbar Starling (*Aplonis crassa*), confined to the Tanimbar Group, in the easternmost Lesser Sundas; the Atoll Starling (*Aplonis feadensis*), found on small islands lying north-west, north and east of the

Bismarck Archipelago; the Yellow-eyed Starling of New Guinea; the Helmeted Myna (*Basilornis galeatus*), found in the Banggai Islands and the Sula Islands, off east Sulawesi; the Bare-eyed Myna (*Streptocitta albertinae*), confined to the Sula Islands alone; the Apo Myna, with a small range on Mindanao, in the south Philippines; the Sri Lanka Hill Myna, locally distributed in the forests of Sri Lanka; and, finally, the Copper-tailed Glossy Starling, confined to the West African rainforest from Sierra Leone east to Ghana. These nine sturnids are generally uncommon and local.

It is notable that the majority of these eight globally threatened and nine Near-threatened species are from islands in the southern Asian region and the Pacific Ocean. Only two African species feature on the list: the Vulnerable Abbott's Starling and the Near-threatened Copper-tailed Glossy Starling.

Unfortunately, the trade in wild birds remains a potential threat to several sturnids, as indicated above, and currently only two members of the family, the Bali Myna and the Superb Starling, reproduce frequently enough in captivity to supply the demand. Ironically, capture for the cagebird trade was a primary cause of the near-extermination of the Bali Myna, and even captive-bred individuals fitted with transponders and released into the wild have been recovered in bird shops. The wild population of the species is currently estimated at just 24 individuals, so that its survival is dependent on the release of birds from captive stocks. A major conservation and recovery programme for the Bali Myna has been in operation since the 1980s. Coordinated by BirdLife International, it has involved the American Association of Zoological Parks and Aquaria, the Jersey Wildlife Preservation Trust and the Indonesian government. The original wild population is now confined to an area of 38 km² in the Bali Barat National Park, in western Bali. There may, however, be some reason for optimism, as a second population has been established on the small island of Nusa Penida, off the south-east coast of Bali. This is derived from 49 released individuals to date and it appears to have adapted to the island's conditions and is breeding. By the year 2008, 16 individuals had been reared on Nusa Penida.

Sturnidae contains some of the world's most endangered species, but in the Common Starling the family also includes one of the world's most numerous birds. The recent history of this species demonstrates, however, that one should not be complacent even about the apparently common members of the family. While the Common Starling's numbers and distribution are increasing in parts of the east and south of its Eurasian range, in western Europe the reverse is the case. The European decline appears to be related to changes in agriculture, whereby reductions in food supply have reduced the survival rate of the species, especially that of individuals in their first calendar-year. In Britain, the population decline of the Common Starling has been of such magnitude that the species, which was once perceived as a serious agricultural, urban and aviation pest, is now placed on the "Red List" of British birds of conservation concern. Furthermore, similar scales of decline have been reported from much of the species' north-west European range, where agricultural intensification has been rampant over the last 30–40 years.

Road traffic as a cause of mortality among wild animal populations has been investigated for relatively few species, and much of the focus has tended to be on mammals as victims. Nevertheless, all animals which cross roads at height below that of a vehicle are at risk, and in one study in India, in which a 5-km stretch of road was monitored for one year, a total of 219 bird casualties was recorded, compared with 42 amphibians, 82 reptiles and 96 mammals. Young mynas were mentioned as being among the more frequent victims. Casual observations elsewhere also suggest that fledglings are particularly at risk from motor vehicles, and a significant number of ring recoveries relate to starlings which have been struck by motor vehicles.

With the formation of permanent human settlements and agricultural activity, large-scale modification of natural habitats began. This was to the detriment of forest-dwelling starlings, although some of the latter have proved resilient. A comparison of the modern fauna of a 4-ha rainforest fragment in the Singapore Botanical Gardens with records from a century ago showed that both the Asian Glossy Starling and the Common Hill Myna were among the survivors, while there were two new starling colonists, the White-vented Myna and the Common Myna. Generally, open-country sturnids and those able to adapt to modified habitats have benefited; some Asian species are essentially commensal with man today. The habit of nesting in structures with religious importance may have led to the acquisition by some species of a new cultural significance, and starlings are among

*Unsustainable exploitation for the cagebird trade has reduced the **Black-winged Myna** to Endangered status. It was formerly common in the plains of east Java, and locally common in central and west Java, but is now rare and very localized throughout. Similar declines have occurred on Bali and Nusa Penida, and there are very few records from Madura or Lombok. A recent survey of 33 historical locations revealed just 32 individuals at three locations. The Black-winged Myna occurs in at least three protected areas, Baluran National Park and Pulau Dua Reserve in Java, and there are a maximum of 24 individuals in Bali Barat National Park, Bali. An introduced population in Singapore is apparently extinct.*

[*Acridotheres melanopterus tertius*, Bali.

*The **Bali Mynas** seen here were among the last wild individuals left before the initiation of the "Bali Starling Recovery Plan" in 1983. This species breeds readily in captivity and good numbers of young have been produced over the years for reintroduction into the Bali Barat National Park, the last remnant of the species natural distribution. However, illegal demand for the cagebird trade has been so high that captive-bred birds have been trapped almost as fast as they are released. In 1999, an armed gang stole almost all the 39 captive birds awaiting release. The wild population fell to just six birds in 2001. A second population has been established on Nusa Penida off south-east Bali, and by 2008 some 49 individuals had produced a total of 16 young. This part of the project is controversial, as the Bali Myna is not native to Nusa Penida. In 2008, the wild population of the Bali Myna was estimated at just 24 individuals.*

[*Leucopsar rothschildi*, Bali. Photo: Ketil Knudsen]

the birds commonly released at Hindu and Buddhist ceremonies (see Relationship with Man). In Africa, Red-winged Starlings which utilize ledges as nest-sites have been nesting on buildings since the nineteenth century, while Tristram's Starling in the Middle East first began to nest on buildings in the 1980s. As a result, both species have now been able to expand their ranges to areas which otherwise lack suitable natural nest-sites.

While man-modified environments may provide new nest-sites in buildings and other constructions, and despite the deliberate provision of nestboxes, nonetheless modification of natural habitats constantly reduces nesting opportunities. In city parks, the regular pruning and removal of rotten branches is detrimental to all secondary hole-nesting animals. Rural human communities which are dependent on fires for cooking and heating preferentially remove dead trees and branches, and it is in these that natural cavities and, in many cases, established nest-holes of barbets and woodpeckers are most likely to occur. Field studies in South Africa have confirmed a reduction in the numbers of breeding birds, including starlings, which are secondary hole-nesters following sustained extraction of fuelwood from particular areas.

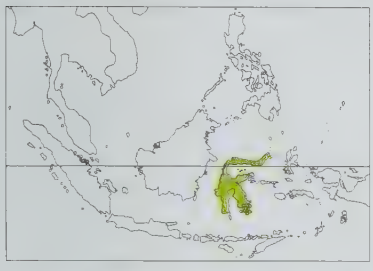
PLATE 40

inches 4



Genus *BASILORNIS* Bonaparte, 1850

1. Sulawesi Crested Myna

Basilornis celebensis

French: Basilorne des Célèbes **German**: Königsatzel **Spanish**: Miná de Célebes
Other common names: Sulawesi/Celebes/King Starling, Short-crested/Celebes (Crested)/Sulawesi Myna

Taxonomy. *Basilornis celebensis* G. R. Gray, 1861, Menado, Makassar, Sulawesi.
May form a superspecies with *B. galeatus* and *B. corythaix*. Monotypic.
Distribution. Sulawesi, including islands of Lembeh, Muna and Buton.

Descriptive notes. 25 cm. Distinctive myna, with feathers of forehead, crown and nape directed to central line to form rigid crest. Forehead to nape and hindneck are glossy violet-blue; white patch on lower ear-coverts, washed with orange posteriorly; upperparts and underparts black, feather tips with green iridescence, feathers at side of breast white with buff wash; tail black, slightly glossy, wings blackish-brown; iris brown-red; bill pale greenish-blue; legs lemon-yellow. Sexes similar, crest slightly longer on male than on female. Juvenile is chocolate-brown with limited iridescence, paler feathers on underparts producing streaked appearance, no orange wash on white areas of plumage. Voice. Calls of several types, described as whistles, squeaks, grunts and warbles; some high-pitched, others prolonged nasal notes.
Habitat. Primary forest and woodland, particularly in hilly areas; reported also from secondary forest, forest edge and clearings. Avoids plantations. Recorded to 1200 m, mostly below 1000 m.
Food and Feeding. Omnivorous; diet includes fruit and animal matter; estimated proportions 44% fruit, 52% invertebrates, 4% small vertebrates. Flocks feed in upper branches with other frugivores, including *Enodes erythrophris*.
Breeding. No published information.
Movements. Apparently resident; presumably moves locally in response to fruiting cycles of trees.
Status and Conservation. Not globally threatened. Restricted-range species: present in Sulawesi EBA. Numerical status uncertain; considered variously as the rarest of the Sulawesi starlings and, conversely, not uncommon. In recent surveys, found to be relatively uncommon in primary forest, very infrequent in secondary forest and modified habitats, and absent from plantations. Occurs in Dumoga-Bone National Park.
Bibliography. van den Berg & Bosman (1986), Blasius (1897), Coates & Bishop (1997), Neumann (1992), Sodhi, Koh *et al.* (2005), Stresemann & Heinrich (1940b), Vorderman (1898a), Walker (2007), Wardill *et al.* (1999), Watling (1983), White & Bruce (1986).

2. Helmeted Myna

Basilornis galeatus

French: Basilorne huppé **German**: Helmatzel **Spanish**: Miná de Yelmo
Other common names: Greater (Crested)/Crested/Sula/(Greater) King Myna, Crested/Greater King Starling

Taxonomy. *Basilornis galeatus* A. B. Meyer, 1894, New Guinea; error = Banggai Islands or Sula Islands.
May form a superspecies with *B. celebensis* and *B. corythaix*. Monotypic.
Distribution. Banggai Is (Peleng and Banggai) and Sula Is (Taliabu, Seho, Mangole), off E Sulawesi.

Descriptive notes. 25 cm. Distinctive myna, with feathers of forehead, crown and nape directed inwards towards mid-line and central feathers elongated to form tall crest. Forehead to nape and hindneck are black with purple sheen; upperparts and underparts black with green iridescence; white patch on lower ear-coverts and side of neck more or less adjoining white patch at side of breast, posterior feathers of neck patch and ventral feathers of breast patch tipped with ochre; wing and tail dark brown; iris brown; bill cream-coloured; legs yellow. Sexes alike. Juvenile has shorter crest than adult, less glossy plumage, with brown chin, dark upper mandible. Voice. Deep booming "poo poo poop" calls the only vocalization reported.
Habitat. Forest, most often in undisturbed areas, also reedswamps, mangroves, and fruiting trees in degraded forest or cultivated areas; to 1000 m.
Food and Feeding. Diet fruit and berries. Usually forages in upper levels of trees, occasionally coming lower. Generally in pairs; flock of 22 individuals once reported.
Breeding. No published information.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Banggai and Sula Islands EBA. Limited data on current status; scarce to moderately common. Has small and fragmented range, and global population likely to be relatively small. Becoming uncommon in Sula lowlands, where loss of the least disturbed forest, its preferred habitat, is a threat. Suitable habitat, particularly in Sula lowlands, should be protected.
Bibliography. Anon. (2008b), Butchart & Stattersfield (2004), Coates & Bishop (1997), David & Gosselin (2002b), Davidson *et al.* (1995), Feare & Craig (1998), Meyer & Wigglesworth (1898), Stattersfield & Capper (2000), White & Bruce (1986).

3. Long-crested Myna

Basilornis corythaix

French: Basilorne de Céram **German**: Molukkenatzel **Spanish**: Miná Moluqueño
Other common names: Ceram Myna/Starling, Seram King Starling

Taxonomy. *Pastor Corythaix* Wagler, 1827, Java; error = Seram, Moluccas.
May form a superspecies with *B. celebensis* and *B. galeatus*. Monotypic.
Distribution. Seram, in S Moluccas.

Descriptive notes. 25 cm; 121–132 g. Distinctive myna, with feathers of crown and nape directed towards mid-line, and elongated to form tall crest of degenerate plumes; tail wedge-shaped. Plumage mostly black, forehead, side of crown, nape, throat and breast with purple iridescence, throat feathers sometimes with fine white tips, mantle, rump and belly with green iridescence; white patch on lower ear-coverts and side of neck and another on side of breast; wing brown, pale buff inner webs on primaries, tail purple-tinged black; iris brown, bare skin around eye dark; bill cream-coloured; legs yellow. Sexes alike. Juvenile undescribed. Voice. Calls include nasal notes interspersed with short piping notes; series of five loud whistles, ascending.
Habitat. Primary forest, also degraded forest; also forest edge, secondary forest, lightly wooded cultivation, and gardens. Lowlands and hills, mostly at 200–900 m.
Food and Feeding. Poorly known. Diet assumed to be fruit, as observed in groups in fruiting trees, and often seen in gardens with *Aplonis mysolensis*. Occurs singly and in pairs.
Breeding. Breeding noted in Jul; presumably monogamous. No other information.
Movements. Resident; any movements presumed very local in nature.
Status and Conservation. Not globally threatened. Restricted-range species: present in Seram EBA. Very poorly known. Appears to be rather local and patchy in distribution. Uncommon in most of range; locally more numerous.
Bibliography. Coates & Bishop (1997), Feare & Craig (1998), Stresemann (1914), White & Bruce (1986).

4. Apo Myna

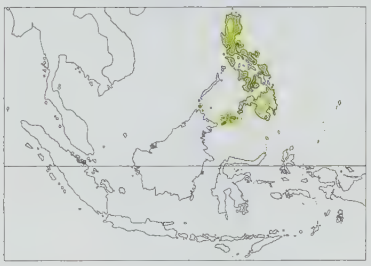
Basilornis mirandus

French: Basilorne de Mindanao **German**: Prachtatzel **Spanish**: Miná de Mindanao
Other common names: Mount Apo Myna, Mount Apo (King) Starling

Taxonomy. *Goodfellowia miranda* E. J. O. Hartert, 1903, Mindanao, Philippines. Monotypic.
Distribution. Mountains of NC & S Mindanao, in S Philippine Is.

Descriptive notes. 30 cm; 110 g. Distinctive myna, forehead feathers compressed into ridge on mid-line, extending as short degenerate plumes on forecrown and longer ones on crown to form permanent wispy crest; large bare patch around eye, tail long and graduated. Plumage mostly black with glossy blue-black feather tips, lower back white; wing dark chocolate-brown, tail blackish-brown; iris yellow to brown, bare yellow skin around eye extends onto cheek; bill yellowish; legs olive-yellow to blackish. Sexes alike. Juvenile similar, but plumage not glossy and has buffish feather edgings. Voice. Call is series of metallic tinkling notes mixed with snapping and gurgling sounds and with squeaky notes like a rusty gate, resembling call of *Sarcops calvus*.
Habitat. Forest and forest edge, above 1250 m.
Food and Feeding. Diet fruits and insects. Occurs singly, in pairs and in small groups.
Breeding. Two nests found, one each in Feb and Jul; bird with enlarged gonads in Feb. Both nests were in old hole of woodpecker (Picidae); one was c. 15 m above ground and contained nest built from twigs and leaves. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Mindanao and the Eastern Visayas EBA. Common at some sites, e.g. Daggayan and Mt Kitanglad, in N, and Mt Apo, in S; has very small and fragmented range, and known from few localities. At present, habitats mostly secure, as terrain largely rugged and inaccessible. Any increase in rate of human intrusion, however, could have a serious adverse effect on this species.
Bibliography. Anon. (2008b), Butchart & Stattersfield (2004), Collar *et al.* (1999), David & Gosselin (2002b), Dickinson *et al.* (1991), Feare & Craig (1998), Kennedy *et al.* (2000), du Pont (1971), Stattersfield & Capper (2000).

Genus *SARCOPS* Walden, 1877



5. Coleto

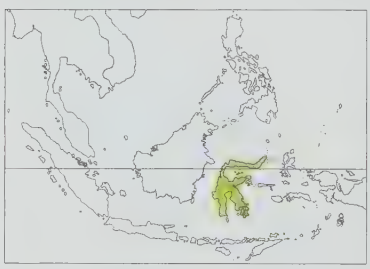
Sarcops calvus

French: Goulin gris **German**: Kahlkopfatzel **Spanish**: Miná Coleto
Other common names: Bald Starling

On following pages: 6. White-necked Myna (*Streptocitta albicollis*); 7. Bare-eyed Myna (*Streptocitta albertinae*); 8. Yellow-faced Myna (*Mino dumontii*); 9. Long-tailed Myna (*Mino kreffti*); 10. Golden Myna (*Mino anais*); 11. Golden-crested Myna (*Ampeliceps coronatus*); 12. Common Hill Myna (*Gracula religiosa*); 13. Southern Hill Myna (*Gracula indica*); 14. Enggano Hill Myna (*Gracula enganensis*); 15. Nias Hill Myna (*Gracula robusta*); 16. Sri Lanka Hill Myna (*Gracula ptilogenys*); 17. Flame-browed Starling (*Enodes erythrophris*); 18. Grosbeak Starling (*Scissirostrum dubium*).

Taxonomy. *Gracula calva* Linnaeus, 1766, Luzon, Philippines.
Three subspecies recognized.
Subspecies and Distribution.
S. c. calvus (Linnaeus, 1766) – N Philippines (Luzon, Polillo, Catanduanes, Mindoro).
S. c. melanonotus Ogilvie-Grant, 1906 – C & S Philippines (Ticao, Samar, Panay, Negros, Cebu, Bohol, Mindanao).
S. c. lowii Sharpe, 1877 – Sulu Archipelago, in SW Philippines.

Descriptive notes. 27 cm; 120–170 g. Distinctive grey-and black sturnid with bare skin covering most of face from base of bill back to side of nape, ear-coverts and cheek, and to top of head (except for narrow central line of bristly black feathers); tail wedge-shaped. Nominate race has upper nape, lower side of neck, chin and throat matt black, lower nape silver-grey; mantle and back black with silver-grey suffusion, rump black with all feathers broadly tipped silvery grey; wing dark brown with blue-green gloss, tail black with blue-green gloss; underparts black, white pectoral tuft (often concealed), flanks with broad grey feather tips; iris pink or dull red to brown, bare skin on head pinkish (area around eye redder when bird excited); bill black; legs dark brown. Sexes alike. Juvenile resembles adult, with silver ruff less pronounced. Race *melanonotus* is smaller than nominate, with black lower mantle and back lacking grey tips (grey of upper mantle forms contrasting pale collar); *lowii* has paler grey nape, mantle, rump and flanks, and brownish-black wings and ventral plumage. Voice. Typical call a metallic click followed by high-pitched "kliing-kliing"; described also as a "delightful combination" of tinkling, bell-like notes mixed with harsh gurgles and sputtering notes. In flight, wings make whining noise.
Habitat. Forest, forest edge, coconut (*Cocos nucifera*) groves and secondary growth, even isolated trees in clearings; below 1500 m.
Food and Feeding. Diet fruit and insects, also flower nectar; captive pair fed young primarily with insects. Forages singly, in pairs and occasionally in small groups, in fruiting trees.
Breeding. Breeds Mar–Sept on different islands; birds with enlarged gonads in Feb; captive individuals in Europe nested in summer. Apparently monogamous. Nest in hole in dead tree or in rotting trunk of coconut palm; in captivity, pair nested in hollow log. Eggs blue with brown and mauve blotches. In captivity, clutch 2–3 eggs, incubation period 13–14 days, nestling period variously 16 days and 23 days; male of one captive pair did most of the feeding of the young. One ringed individual survived for 5 years in the wild.
Movements. Presumed resident; most ringed individuals recaptured close to ringing site, but one moved 175 km.
Status and Conservation. Not globally threatened. Common in much of range. Formerly hunted for food in some regions. Widely kept as a cagebird, as it is a noted mimic of human speech. Occurs in Quezon National Park, on Luzon.
Bibliography. Amadon (1956), Delacour & Mayr (1946), Dickinson *et al.* (1991), Gonzales & Rees (1988), van't Hart (1978, 1980), Kennedy *et al.* (2000), McClure (1998), McGregor (1907), Peck (1983), du Pont (1971), du Pont & Rabor (1973), Rand (1951a), Rand & Rabor (1960), Rayner (1986), Rens (1978), Ripley & Rabor (1958).



Genus *STREPTOCITTA* Bonaparte, 1850

6. White-necked Myna

Streptocitta albicollis

French: Streptocitte à cou blanc **German**: Weißhalsatzel **Spanish**: Miná Cuelliblanco
Other common names: Buton/Sulawesi/Celebes/Vieillot's Myna/Starling/Magpie

Taxonomy. *Pica albicollis* Vieillot, 1818, New Caledonia; error = Buton or Muna Islands, Sulawesi.
May form a superspecies with *S. albertinae*. Two subspecies recognized.
Subspecies and Distribution.
S. a. torquata (Temminck, 1828) – N & E Sulawesi, including Lembeh and Togian Is.
S. a. albicollis (Vieillot, 1818) – S & SE Sulawesi, Muna and Buton.

Descriptive notes. c. 50 cm, including tail of c. 25–30 cm. Large myna with very long, graduated tail; elongated head feathers of waxy appearance, upward-pointing feathers of lores and nostril region producing effect of short crest on forehead. Nominate race has head black, glossed with purple and blue; mantle and breast pure white, producing broad collar, rest of body plumage black with steel-blue and green iridescence, especially on rump and belly; wing black with purple sheen; tail black with slight gloss, and cross-barring visible from certain angles; iris brown, bare circumorbital skin dark; bill black basally, distal half yellow; legs black. Sexes alike. Juvenile differs from adult in having smaller crest, shorter tail, and less yellow on bill. Race *torquata* is very like nominate, but has longer, all-black bill and shorter wing and tail. Voice. Song, from exposed perch, a clear whistling "towee". Calls reminiscent of those of drongos (*Dicrurus*), with twanging nasal notes and harsh rasping sounds; penetrating "keee" alarm. Loud whirring wing noise in flight.
Habitat. Primary forest and secondary forest of various types; very infrequently in modified habitats and plantations. Sea-level to 1200 m.
Food and Feeding. Diet primarily fruit, also invertebrates, occasionally small vertebrates (lizards); estimated proportions 78% fruit, 21% invertebrates, less than 1% vertebrates. Forages mainly in middle canopy; favours dead isolated trees as perches. Strong flier, readily crossing open areas. Usually in twos or threes, occasionally in small groups of up to five individuals; may join mixed-species flocks.
Breeding. Breeds Sept–Oct. Presumed monogamous. Nest in hole of dead tree. No other information.
Movements. Only local movements reported.
Status and Conservation. Not globally threatened. Very poorly known. Widespread and fairly common to common; relatively common in primary and secondary forest, much less so in other habitats. Occurs in Lore Lindu National Park.
Bibliography. Blasius (1897), Coates & Bishop (1997), Holmes (1979), Meyer & Wigglesworth (1898), Sodhi, Koh *et al.* (2005), Stresemann & Heinrich (1940b), Vorderman (1898a), Walker (2007), Watling (1983), Wennrich (1982), White & Bruce (1986).

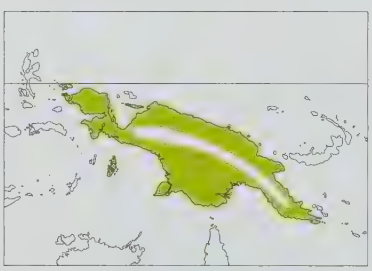
7. Bare-eyed Myna

Streptocitta albertinae

French: Streptocitte des Sula **German**: Sulaatzel **Spanish**: Miná Caricalvo
Other common names: Sula/Schlegel's Myna, Sula Magpie, Sula/Bare-eyed/Albertina's Starling

Taxonomy. *Charitornis albertinae* Schlegel, 1865, Sula Islands, Moluccas.
May form a superspecies with *S. albicollis*. Monotypic.
Distribution. Sula Is (Taliabu, Mangole), E of Sulawesi.

Descriptive notes. 45 cm, including tail of c. 25 cm. Large myna with very long, strongly graduated tail; bare, corrugated skin from lores and broad area around eye to chin and upper throat. Has forehead to nape and mantle, and underparts (except lower region) pure white, back, wing and tail black with greenish gloss, some purple iridescence on back; flanks, lower belly and undertail-coverts glossy black with green iridescence; iris light brown, light grey or red, bare facial and throat skin blackish; bill and legs yellow. Sexes alike. Juvenile has forehead mottled with dark brown feathers. Voice. Call resembling sound made by a squeaky gate, in descending series typically of 5 notes, the only vocalization described.
Habitat. Recorded in degraded forest and in open forest and cultivated areas; status in intact forest unclear. Lowlands, below 250 m.
Food and Feeding. Diet thought to be mainly fruit. Seen mostly in middle and upper levels of large trees; sometimes in smaller trees. Occurs mainly in pairs, less often singly or in trios.
Breeding. No information.
Movements. No information.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Banggai and Sula Islands EBA. Very poorly known. Has a very small global range, within which it is local and uncommon. Apparent tolerance of secondary and degraded habitats indicates that it is not at imminent risk.
Bibliography. Anon. (2008b), Butchart & Stattersfield (2004), Coates & Bishop (1997), Davidson *et al.* (1995), Feare & Craig (1998), Meyer & Wigglesworth (1898), Stattersfield & Capper (2000), White & Bruce (1986).



Genus *MINO* Lesson, 1827

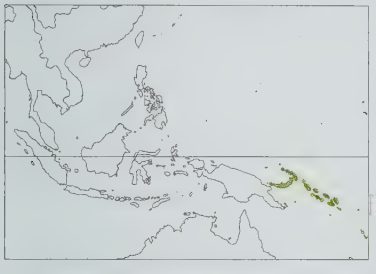
8. Yellow-faced Myna

Mino dumontii

French: Mino de Dumont **German**: Papuaatzel **Spanish**: Miná Carigualdo
Other common names: Orange-faced Grackle, Orange-faced/Papuan/Long-tailed(!) Myna

Taxonomy. *Mino Dumontii* Lesson, 1827, Dorey, north-west New Guinea.
Sometimes treated as conspecific with *M. kreffti*; populations of that species from SW Bismarcks appear morphologically closer to present species than to other populations of *M. kreffti*, suggesting that separate species status may require reassessment. Monotypic.
Distribution. West Papuan Is (Waigeo, Batanta, Salawati), New Guinea and many small offshore islands (except those off SE coast), and Aru Is.

Descriptive notes. 25 cm; mean 217 g. Large, short-tailed myna with much of head unfeathered, having large bare patch above, behind, below and, less extensively, in front of eye, as well as bare patch on chin and side of throat; feathers of forehead, central crown, neck and upper mantle, and throat small and lanceolate. Feathers from forehead to central crown, nape and hindneck and upper mantle, also on central throat, black with purple gloss, usually small white flecks on side of neck produced by white filoplumes (sometimes forming more extensive patches); rest of mantle and back black with greenish gloss, rump and uppertail-coverts white; wing and tail black and glossy, white wing patch formed by white area on inner web of outer primary P9, both webs of P4–P8 and outer web of P3; breast and belly black with greenish gloss, lower belly deep golden-yellow, undertail-coverts white; iris orange-yellow, mottled and flecked with black, some regional variation in iris coloration (often brown in S New Guinea, but in N may be dark brown with or without gold spots); bare head skin orange-yellow; bill and legs orange-yellow. Sexes alike. Juvenile has paler facial skin and paler golden lower belly than adult. Voice. Calls loud nasal growling and croaking sounds, sometimes with quality reminiscent of human conversation; in SE of range (Port Moresby) most calls are disyllabic, whereas elsewhere on mainland calls of three or more syllables predominate. Captives mimic human speech and other sounds.
Habitat. Forest of various types, including rainforest, swamp-forest and monsoon forest; also forest edge and partly cleared areas, and will venture into savanna. Generally in lowlands and hills below 800 m, but in E half of New Guinea recorded at up to 1800 m.
Food and Feeding. Diet mainly fruit, also insects. Often feeding on fruit and berries in company of *M. anais* or other frugivores. Gleans caterpillars (Lepidoptera); also hawks insects from high perches. Usually in pairs, also in small groups, occasionally in larger flocks.



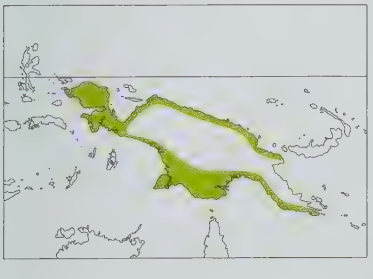
Breeding. Recorded in Aug–Sept and Jan–Apr, suggesting that breeding extends from middle dry season to early wet season. Apparently monogamous, with long-term, possibly lifelong pair-bond. At one nest three birds carried nest material and all three may have fed young, suggesting possible co-operative breeding. Nest of dry sticks, also twigs with green leaves, built in tree hole usually 10–30 m above ground, one nest in base of bird's-nest fern (*Asplenium nidus*) on horizontal branch of dead tree; in captivity, used nextbox lined with straw and strips of paper. Clutch 1–2 eggs, light blue with pale grey and red-brown markings; in captivity, incubation primarily by female, period 14 days, chicks fed by both sexes, nestling period for one brood c. 40 days, only one surviving parent feeding young.
Movements. Resident.
Status and Conservation. Not globally threatened. Widespread and common in New Guinea. Exploited to some degree, as specimens of this species do appear regularly in the pet trade.
Bibliography. Amadon (1956), Beehler *et al.* (1986), Bell (1972b), Coates (1990), Diamond (2002), Draffan (1977b), Eck (2001), Halliday (1984), Hartert (1930), Madarász (1897), McCarthy (2006), Mees (1982), Niznik & Vinett (1997), Ogilvie-Grant (1915), Peckover (1975), Rand & Gilliard (1967).

9. Long-tailed Myna

Mino kreffti

French: Mino de Krefft **German**: Bismarckatzel **Spanish**: Miná de las Bismarck

Taxonomy. *Gracula kreffti* P. L. Sclater, 1869, Solomon Islands.
Sometimes treated as conspecific with *M. dumontii*; shorter-tailed birds from SW Bismarcks (New Britain and Umboi) described as race *giliau*, and smaller birds from E Solomons (Guadalcanal and Malaita) described as *sanfordi*; however, while birds from SW Bismarcks appear to show moderately distinctive morphological traits compared with populations from N Solomons, they are more closely similar to birds from New Guinea currently separated as *M. dumontii*, suggesting that treatment as separate species may not be justified; further study needed at both specific and subspecific levels. Currently treated as monotypic.
Distribution. Bismarck Archipelago and N & C Solomon Is (SE to Guadalcanal and Malaita).



Descriptive notes. 30 cm; 170–215 g. Large myna with large patch of unfeathered skin before, above and below eye and extending to a point behind eye (on nape side. Feathered part of head to hindneck, throat and breast black, glossed purple, usually a few white filoplumes behind bare patch; mantle and back black, glossed greenish-blue, uppertail-coverts white and elongated; tail black, some gloss; wing black with variable gloss, outer primary P9 with white patch on inner web, P4–P8 with white on both webs, P3 with white spot on inner web and primary P2 with white spot on outer web, all forming large white patch (up to 4 cm broad) conspicuous in flight; belly black, glossed greenish-blue, lower belly golden, forming narrow band; undertail-coverts white; iris orange-yellow to orange, bare facial skin orange-yellow to deep orange; bill orange-yellow to deep orange; legs yellow to yellow-orange. Sexes alike. Juvenile has iris yellowish, tinted brown. Voice. Extended whistles and squawks, with loud, high-pitched whistles most like those of *M. anais*. Calls may contain a number of distinctive notes; some regional variations reported.
Habitat. Forest, especially forest edge, also forest remnants, plantations and secondary growth near villages; visits gardens. Generally below 500 m; occasionally to 1100 m in Solomons.
Food and Feeding. Diet fruit; stomach contents included slices of soft fruit, and hard-seeded berries. Occurs singly and in pairs. Forages mostly in canopy; perches for long periods on exposed bare branches of trees.
Breeding. Recorded at nest-holes throughout year. Monogamous; partners remain together throughout year. Nest built in tree hole or in broken palm; clutch of 2 eggs reported, pale blue with grey and red-brown markings. No other information.
Movements. Resident.
Status and Conservation. Not assessed, as often treated as a race of *M. dumontii*. Probably not globally threatened. Common. Described as abundant on Bougainville I, and one of the most obvious and most vocal birds in forest across its range.
Bibliography. Blaber (1990), Bregulla (1992), Cain & Galbraith (1956), Dutson (2008b), Eck (2001), Hadden (1981, 2004), Heinroth (1903), Mayr & Diamond (2001), Sclater (1869), Schodde (1977).

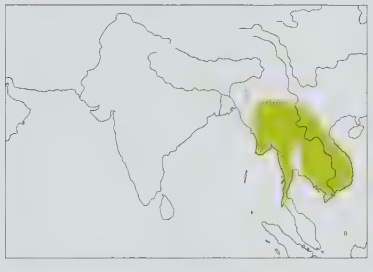
10. Golden Myna

Mino anais

French: Mino d'Anaïs **German**: Orangeatzel **Spanish**: Miná Dorado
Other common names: Golden-breasted Myna; Western Golden Myna (*anais*); Eastern Golden Myna (*orientalis* and *robertsoni*)

Taxonomy. *Sericulus Anaïs* Lesson, 1839, New Guinea. Three subspecies recognized.
Subspecies and Distribution.
M. a. anais (Lesson, 1839) – West Papuan Is (Salawati) and NW New Guinea.
M. a. orientalis (Schlegel, 1871) – coastal N New Guinea E to Huon Peninsula.
M. a. robertsoni D'Albertis, 1877 – S New Guinea E to Milne Bay.

Descriptive notes. 25 cm; mean 152 g. Medium-sized, distinctively patterned myna with patch of bare circumorbital skin extending to form a blue wedge behind eye. Nominate race has head, mantle and upper back black, feathers broadly tipped with glossy oily green, broad collar on hindneck and side of neck creamy orange; feathers of lower back to uppertail-coverts elongated and degraded, with deep orange tips; wing dark brown, white patch on inner webs of outer and innermost primaries (P1 and P9) and on both webs of other primaries, forming conspicuous wingbar in flight; tail black with slight green gloss; chin, throat and belly black with oily-green gloss, breast feathers black with broad orange-yellow tips, lower belly and vent yellow, undertail-coverts creamy white; iris yellow, bare circumorbital skin dark blue; bill and legs yellow. Sexes alike. Juvenile has yellow areas of plumage duller than adult and mottled with black, underparts black with yellow scaling. Races differ in plumage pattern: *orientalis* has forehead and crown glossy-yellow orange, with orange-yellow stripes extending down on each side of hindcrown to join glossy orange-yellow collar; *robertsoni* has entire crown and nape glossy orange. Voice. Song a short whistled series of rising and falling notes, described as reminiscent of sound made by a squeaky bicycle. Alarm call a high-pitched metallic "queelie" or rasping "whaa"; other nasal or squeaky calls reported.
Habitat. Lowland forest below 600 m, including monsoon forest; also forest edge and partially cleared areas, provided that tall trees still present.
Food and Feeding. Diet apparently only fruit. Forages primarily in upper canopy. Occurs typically in pairs, occasionally in small flocks; may join groups of *M. dumontii*.
Breeding. Breeding season believed long, from end of wet season through dry season; activity at nest-holes Feb–Oct, but holes may be used for roosting as well as for nesting. Monogamous; close association of partners and allopreening suggest long-term pair-bond. Nest placed 10–30 m above ground in tree hole, generally at forest edge or in clearing. Clutch size not known, but one nest contained two young; young fed by both adults, perhaps entirely with fruit, and long nestling period likely. No further information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Widespread and fairly common. Possible presence on Yapen, in Geelvink Bay, requires investigation. Apparently readily available in Asian bird trade.
Bibliography. Beehler *et al.* (1986), Bell, H.L. (1984b), Coates (1990), Curzon & Mekke (1993), Hartert *et al.* (1936), Madarász (1899), McCarthy (2006), Ogilvie-Grant (1915), Rand & Gilliard (1967), Rothschild (1921).



Genus *AMPELICEPS* Blyth, 1842

11. Golden-crested Myna

Ampeliceps coronatus

French: Mainate couronné **German**: Kronenatzel **Spanish**: Miná Coronado

Taxonomy. *A[mpeliceps] coronatus* Blyth, 1842, Tenasserim, south Myanmar.
Monotypic.
Distribution. NE India (Cachar), and from C & S Myanmar E to S China (SW Yunnan), Laos and Vietnam, S to S Thailand and Cambodia.

Descriptive notes. 20 cm; 78–99 g. Medium-sized myna with short square-ended tail, and stiff feathers at base of upper mandible directed forwards over nostrils, bare skin around eye and extending back to form point behind eye. Male has golden-yellow forehead to crown and nape forming crest, and extending anteriorly down to chin and centre of throat; rest of plumage black, glossed with purple on side of face, mantle and chest, glossed blue-green on rump and upper belly; wing black, white patch on inner web of outer six primary feathers, yellow patch on outer web of primaries P4–P9; tail black; iris dark brown, bare skin around eye yellowish-pink; bill yellow, bluish base of lower mandible; legs dull orange. Female is like male but with less gold on head, and with only narrow central strip of golden-yellow on chin and throat. Juvenile is duller and browner than adult, with pale lores, wing patch and throat, faintly streaked below; acquires golden-yellow feathers gradually. Voice. Calls include high, slightly slurred bell-like notes; voice similar to that of *Gracula religiosa* but higher in pitch.
Habitat. Lowland evergreen forest, also deciduous and mixed woodland, open forest, and cleared areas with tall relict trees; in SE Thailand found only in intact primary forest. Lowlands and foothills to c. 800 m.
Food and Feeding. Diet primarily fruit; probably also takes insects. Forages in pairs or in small groups, primarily in canopy.
Breeding. Season Apr–Aug. Monogamous. Nest a rough lining of grass in tree hole 5–15 m above ground. Clutch 3–4 eggs, blue-green with brown blotches concentrated at thicker end; in captivity, incubation by female alone, for 14–15 days, chicks fed by both parents, young fledged after 25–26 days. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Poorly known in the field. Thought to be scarce to locally common in most of range; rare and irregular in peninsular Thailand; rare and very local in NE India. Recorded also in NW Peninsular Malaysia, but status there unclear; no recent records. Quite frequently reported in bird trade in Thailand, although apparently still common in N Thailand. Vulnerable to deforestation.
Bibliography. Ali & Ripley (1972), Chen Fuguan *et al.* (1998), Junge & Kooiman (1951), Lekagul & Round (1991), Meyer de Schauensee (1984), Rasmussen & Anderton (2005a, 2005b), Robson (2000), Smythies (1986), Sontag (1998), Wells (2007).

Genus *GRACULA* Linnaeus, 1758

12. Common Hill Myna

Gracula religiosa

French: Mainate religieux **German**: Beo **Spanish**: Miná Religioso
Other common names: (Eastern) Hill Myna, Talking Myna, Common Grackle

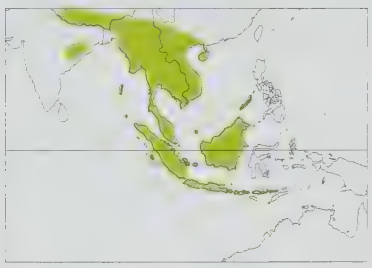
Taxonomy. *Gracula religiosa* Linnaeus, 1758, Asia = Java.

Often treated as conspecific with *G. indica*, *G. enganensis* and *G. robusta*. Birds from Flores (Lesser Sundas), described as race *mertensi*, considered inseparable from *venerata*. Seven subspecies recognized.

Subspecies and Distribution.

G. r. intermedia Blyth, 1845 – N & NE Indian Subcontinent E to Myanmar and S China (including Hainan I), S to N peninsular Thailand, Cambodia and Indochina.

G. r. peninsularis Whistler & Kinnear, 1933 – EC India (Orissa and SE Madhya Pradesh).



G. r. andamanensis (Beavan, 1867) – Coco Is (S of W Myanmar), Andaman Is and Nicobar Is.

G. r. religiosa Linnaeus, 1758 – S Thailand, Peninsular Malaysia, Sumatra, Bangka I, Belitung, N Natunas, Borneo, Java and Bali.

G. r. batuensis Finsch, 1899 – Batu Is and Mentawai Is, off W Sumatra.

G. r. palawanensis (Sharpe, 1890) – Palawan (W Philippines).

G. r. venerata Bonaparte, 1850 – Lesser Sundas from Lombok and Sumbawa E to Pantar and Alor. Introduced populations (probably nominate race) established in SE USA (Florida), Puerto Rico and Hawaii.

Descriptive notes. 30 cm; 161–229 g. Large black myna with prominent bare yellow patches of skin on head. Nominate race has bare yellow patch below eye, and line of bare yellow skin from just behind eye backwards around nape, where it extends into two pendulous yellow wattles; plumage mostly black, with purple gloss on head, throat and mantle, and turquoise to bronzy sheen on rump and breast; lower belly glossy turquoise; wing black with purple gloss, outermost large primary (P9) with white patch on inner web, primaries P4–8 with white patch on both webs, primary P3 with white on outer web only; iris brown; bill orange to red, yellow tip; legs chrome-yellow. Sexes alike. Juvenile much less glossy, with wattles smaller. Races differ mainly in pattern of bare patches on head, in nature of glossiness of plumage, and in size: *intermedia* smaller than nominate, more bronzy on breast and upper back, bill smaller, upper mandible less curved, bare skin of eye and nape joined but not extending around back of nape; *peninsularis* slightly smaller than previous, with smaller and finer bill; *andamensis* has bare skin of eye and nape joined or only narrowly separated, white in wing sometimes extending to primary P2, bill longer and less curved than that of nominate; *batuensis* larger than nominate; *palawanensis* slightly smaller than nominate, bill shorter but deep, back, rump and underparts more bluish and bronzy, bare patches below and behind eye separated, wattles slightly separated; *venerata* glossier than nominate, bare skin behind eye larger, joined to broad wattles, and extending upwards to hindcrown. Voice. Four categories of call described: "chip-calls", short descending squeaks, loud and piercing, given in alarm or for long-distance communication with conspecifics; "um-sounds", soft nasal noises as close-range contact; "whisper-whistles", soft high-pitched sounds from perched individuals, possibly equivalent of song; and calls comprising a great variety whistles, wails, croaks and shrieks, given by individuals on seeing or hearing each other. Imitates conspecifics (but not sounds of other bird species or other animals). Captives famed for accurate imitation of human voice, but learning dependent on close association with human care-giver and isolation from own species; in aviaries, vocalization and mimicry an expression of dominance.

Habitat. Regions with large trees, evergreen or deciduous, high rainfall and high humidity; edges of forest and disturbed areas often utilized, also cultivated areas where large trees maintained. Favours forest patches over dense forest. Lowlands and hills, mainly to 1370 m; sometimes to 2000 m in Indian Subcontinent.

Food and Feeding. Diet primarily fruit, also nectar, and insects and other small animal food, even small vertebrates (lizards). Figs (*Ficus*) an important component of diet, also other fruit (including spiny palm *Orchosparra tigillaria*) and berries up to 2 cm in diameter; stones regurgitated (and may assist in plant's seed dispersal). Nectar recorded as taken from flowers of *Bombax*, *Erythrina*, *Grevillea* and *Helicteres isora*. Geckos (Gekkonidae) taken on tree trunks, especially when feeding young. Frequently feeds in flowering trees, when face becomes dusted with pollen (may play a role in pollination). Insects gleaned from foliage; winged termites (Isoptera) hawked in flight. Often in pairs; sometimes in flocks, occasionally large numbers gathering at fruiting trees.

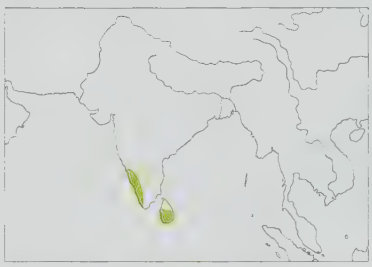
Breeding. Season Apr–Jul in India, Sept–Jul in SE Asia (mainly Jan–Jul in Thailand, Feb-Jul in Malaysia); recorded in Dec in Java, Aug in Philippines; up to three broods per season. Monogamous; may pair for life. Nest built by both sexes, a pad of leaves, small twigs and feathers, with fresh leaves added during incubation, placed at least 10 m above ground in hole in tall tree at edge of clearing or in open area, often old hole of woodpecker (Picidae) or parakeet (Psitaccidae); may nest in association with other species, e.g. Vernal Hanging-parrot (*Loriculus vernalis*); nest reused in successive years. Clutch 2–3 eggs, blue to greenish blue, with variable reddish-brown and chocolate-brown blotches; incubation by both sexes, female doing greater share of the work, period 13–17 days; chicks fed by both parents, nestling period 25–28 days; as adults begin new brood soon after young leave nest, young presumably take short time to reach independence. At nests in Thailand during 1991–1998, 308 (79%) of 389 eggs hatched but only 37 young fledged (12% of hatchlings), with 49 chicks lost to predators, at least 188 taken by humans and 34 lost through unknown cause; in following year at protected nests, hatching success again 80%, but 44 chicks fledged from 55 eggs, with 25% of chicks lost to predators or through unknown cause; clearly, human interference was the major factor influencing breeding success at this site. Parasitized by Common Koel (*Eudynamys scolopacea*) in Philippines.

Movements. Resident; local movements, when large flocks concentrate at fruiting trees.

Status and Conservation. Not globally threatened. Common in Indian Subcontinent; uncommon to locally fairly common in SE Asia; in Lesser Sundas generally local and uncommon, but perhaps more numerous on Flores. Introduced (probably nominate race) in SE USA (Florida), Puerto Rico and Hawaii; also reportedly on Taiwan, but possibly not established there, nor in Florida nor Hawaii; introduction attempt failed on Christmas I (Indian Ocean). Early reports from St Helena (S Atlantic Ocean) may have been erroneous. Has declined throughout natural range owing to heavy exploitation for cagebird trade. Serious concern over reduction of wild populations, and, although this species can be bred successfully in captivity, this unlikely to be feasible on a scale large enough to satisfy demand. Formerly captured for food in NE India; today heavily exploited for cagebird industry, with nestlings collected from artificial nest-sites (such as split bamboos) and natural nest-sites raided. In N India, was a favoured species for local bird-keepers, and other starlings were sometimes dyed black to resemble it. Legal exports from Delhi airport (N India) during 1983–1990 recorded as 26,000 "mynas", but exact species not mentioned; other observers had estimated that, in 1979 alone, 15,000–25,000 "hill mynas" were collected for trade, most as nestlings or fledglings. Estimated 200,000 individuals legally exported from Thailand in period 1967–1971, and rate of human exploitation considered unsustainable in that country.

Bibliography. Ahmed (1997), Ali & Ripley (1972), Archawaranon (1994, 2003, 2005a, 2005b), Archawaranon & Techatraisak (2002), Bertram (1968, 1969, 1970, 1976), Boosey (1957), Chen Fuguan *et al.* (1998), Coates & Bishop (1997), Dickinson *et al.* (1991), Halbaken (1959), Hoogerwerf & Rengers Hora Siccama (1938), Kennedy *et al.* (2000), Klatt & Stefanski (1974), Lekagul & Round (1991), Lever (2005), Lin Rueyshing (2001), Majumdar (1978, 1984a), van Marle & Voous (1988), Mees (1986), Menon (1994), Oberholser (1917b, 1919a, 1919b, 1932), Ouse (1980), duPont (1971), Rahman & Haque (1992), Rasmussen & Anderton (2005b), Rensch (1931), Riley (1929), Ripley (1944), Robson (2000), Smythies & Davison (1999), Sontag (1998), Sontag & Louette (2007), Stresemann (1912b), Wells (2007), White & Bruce (1986).

13. Southern Hill Myna



Gracula indica

French: Mainate indien **German**: Indienbeo **Spanish**: Miná Indio

Taxonomy. *Eulabes indicus* Cuvier, 1829, India.

This species, *G. enganensis* and *G. robusta* often treated as conspecific with *G. religiosa*. Monotypic.

Distribution. SW India (C & S Western Ghats) and S region of Sri Lanka.

Descriptive notes. 23–25 cm; 126 g. Medium-sized black myna with bare patch below eye clearly separated from bare postorbital skin, which extends back to nape, where there is a wattle, and forwards over crown to a level opposite eye; wattles on each side do not make contact in mid-line. Plumage mostly black, with forehead and centre of crown glossed purple, body glossed purple and oily green; wing and tail black, white patch on inner web of outer large primary P9, on both webs of P4–P8 and on outer web of P3, forming conspicuous white window in flight; iris dark brown, bare skin on head yellow; bill orange, yellow tip; legs yellow. Sexes alike. Juvenile duller and has smaller and paler wattles. Voice. Loud, piercing musical whistles, and harsh guttural notes; alarm a loud squeaky wheeze, close contact call a soft, lilting squeak; calls generally higher-pitched and less variable than in *G. religiosa*, some resembling sound made by squeaky door hinge, and seem to lack lower-pitched elements of congeners. Wings produce loud hum in flight.

Habitat. Wooded country, including evergreen forest and well-wooded cultivated areas; generally between 300 m and 1300 m, locally to 1700 m.

Food and Feeding. Diet mainly fruit and nectar: fruit of figs (*Ficus*) and berries of sapu tree (*Michelia champaca*) recorded in diet; nectar taken from *Bombax*, *Erythrina*, *Grevillea* trees, and the forest shrub *Helicteres isora*. Forages mainly in treetops. Generally in pairs or small groups; may flock at flowering trees.

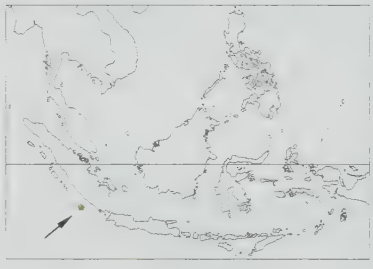
Breeding. Season Feb–May in S India and Mar–Sept (mainly Apr–May) in Sri Lanka. Monogamous. Nests in tree hole, usually very high up; clutch 2–3 eggs, greenish blue with brown spots. No other information.

Movements. Resident; some local seasonal movements evident, based on records outside usual range.

Status and Conservation. Not assessed, as often treated as a race of *G. religiosa*. Probably not globally threatened. Locally common. Caught in large numbers for cagebird trade, although has a lesser reputation as a talker, perhaps because most individuals are captured as adults, but also because voice appears to lack lower-pitched elements.

Bibliography. Ali & Ripley (1972), Feare & Craig (1998), Grimmett *et al.* (1998), Henry (1971), Legge (1880), Maringue (1991), Rasmussen & Anderton (2005a, 2005b), de Silva Wijeyeratne (2006), Steinle (1978), Wait (1925).

14. Enggano Hill Myna



Gracula enganensis

French: Mainate d'Enggano **German**: Engganobeo **Spanish**: Miná de Enggano

Taxonomy. *Gracula enganensis* Salvadori, 1892, Engano Island, Sumatra.

This species and *G. indicus* and *G. robusta* often treated as conspecific with *G. religiosa*. Monotypic.

Distribution. Enggano I, W of S tip of Sumatra.

Descriptive notes. 27 cm. Rather large black myna with small patch of bare skin below eye, bare postorbital skin leading to large wattles which almost join on nape, but no bare skin on crown; feathers of side of head directed upwards to form tuft. Plumage is mostly black, head, neck and mantle strongly glossed purple, rump glossed turquoise; underparts duller, less glossy; wing and tail brownish-black, white patches on inner web of outer primary P9 and both webs of all other primaries, forming large window (larger than that on *G. religiosa*); iris dark brown, bare facial skin and wattles yellow; bill deep and shorter than that of congeners, orange to red with yellow tip; legs yellow. Sexes alike. Juvenile undescribed. Voice. No information.

Habitat. Forested areas.

Food and Feeding. Diet presumably mainly fruit; probably also nectar and insects.

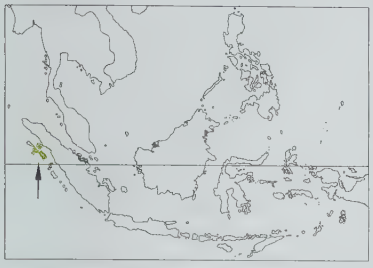
Breeding. No confirmed information.

Movements. Resident.

Status and Conservation. Not assessed. Very poorly known; conservation status not well studied, as often regarded as a race of *G. religiosa*. Tiny global range suggests that population is likely to be small, and this could be a cause for concern; field study required.

Bibliography. Feare & Craig (1998), Hoogerwerf (1963), Stresemann (1912b).

15. Nias Hill Myna



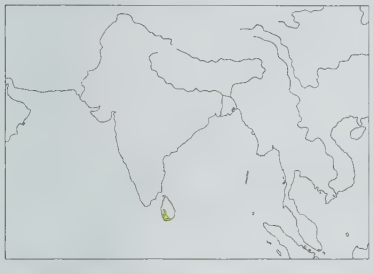
Gracula robusta

French: Mainate de Nias **German**: Niasbeo **Spanish**: Miná de la Nias

Taxonomy. *Gracula robusta* Salvadori, 1887, Nias Island.

This species, *G. indicus* and *G. enganensis* often treated as conspecific with *G. religiosa*. Monotypic.

Distribution. Banyak Is (Babi, Bangkaru and Tuangku) and Nias I, off NW Sumatra.



Descriptive notes. 32 cm. Large black myna with heavy and strongly curved bill, and feathers in front of eye directed inwards and upwards, on crown flattened on central line; large patch of bare skin below eye, a separate post-orbital patch forming large wattles on nape which meet in mid-line. Plumage is mostly black, glossed purple on forehead and crown, body with purple gloss, tinged turquoise on rump and belly; wing and tail brownish-black, very large white patches in primaries extending almost to feather bases, white also on secondaries (close to rachis); iris brown, bare facial skin and wattles yellow; bill red, base orange-red and tip yellow; legs yellow. Sexes alike. Juvenile undescribed. Voice. No information; reputed to be an excellent mimic of human speech.
Habitat. Forest in hills away from coast.
Food and Feeding. No published information.
Breeding. In breeding condition in Jun. No other information.
Movements. Resident.
Status and Conservation. Not assessed. Very poorly known; conservation status not well studied, as often regarded as a race of *G. religiosa*. On some islands of this species' small global range, forest clearance, coupled with trapping for the cagebird trade, may have had a serious impact on the population.
Bibliography. Dymond (1994), Feare & Craig (1998), Ripley (1944), Stresemann (1912b).

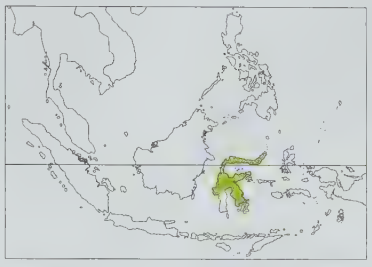
16. Sri Lanka Hill Myna

Gracula ptilogenys

French: Mainate de Ceylan **German**: Dschungelbeo **Spanish**: Miná Cingalés
Other common names: Sri Lanka Myna, Ceylon Myna/Grackle

Taxonomy. *Gracula ptilogenys* Blyth, 1846, Sri Lanka. Monotypic.
Distribution. SW Sri Lanka.

Descriptive notes. 25 cm. Relatively small black myna, feathers on forehead projecting upwards and forwards, forming small spiky tufts; two separate wattles on nape. Male plumage is essentially black, with narrow band of velvety feathers surrounding eye, body with strong purple gloss; outermost large primary (P9) has white patch on inner web, P4–P8 with white patches on both webs and primary P3 with much-reduced patch on inner web, producing large white wing patch in flight; iris greyish-white with brown speckles, apparently sometimes whitish; nuchal wattles yellow; bill orange-red, bluish to blackish base; legs deep yellow. Female is very like male in plumage, but lower mantle glossed green (not purple), iris coloration always yellowish-white or whitish. Juvenile is browner and less glossy than adult, bill base paler, nuchal wattles much smaller. Voice. Calls include piercing downslurred whistles, also croaking and guttural notes. Captive individuals are good mimics, including imitations of human speech. Wings produce musical hum in flight, audible from moderate distance.
Habitat. Forest or wooded areas, especially rainforest, primarily in tall trees; ventures also into estate plantations and village gardens. To at least 2000 m in hills.
Food and Feeding. Diet primarily fruit, also seeds; fruits of figs (*Ficus*) and wild nutmeg (*Myristica*) recorded. Generally seen in pairs.
Breeding. Season Feb–May, sometimes also Aug–Sept. Monogamous. Nest in tree hole, often above 10 m, cavity unlined, or lined with grass and other vegetation. Clutch 2 eggs. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Sri Lanka EBA. Uncommon and local; common in some places. This species' ability to persist in some secondary and degraded habitats suggests that it may not be at immediate risk. Nestlings often taken for cagebird trade.
Bibliography. Ali & Ripley (1972), Anon. (2008b), Butchart & Stattersfield (2004), Feare & Craig (1998), Grimmett *et al.* (1998), Henry (1971), Jayasekara *et al.* (2003), Legge (1880), Rasmussen & Anderton (2005b), Stattersfield & Capper (2000), Stresemann (1912b), Wait (1925).



Genus *ENODES* Temminck, 1839

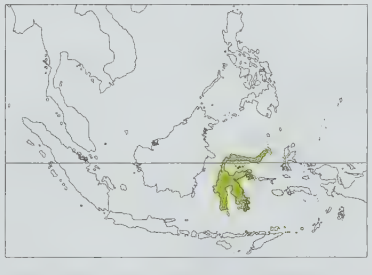
17. Flame-browed Starling

Enodes erythrophris

French: Énode à sourcils rouges **German**: Rotbrauenstar **Spanish**: Estornino Cejirrojo
Other common names: Fiery-browed Myna/Menado Myna, (Celebes) Enodes Myna/Starling, Red-browed Starling

Taxonomy. *Lamprotornis erythrophris* Temminck, 1824, Menado, Sulawesi.
Races possibly represent no more than minor colour variants, and species often treated as monotypic; further study needed. Three subspecies provisionally recognized.
Subspecies and Distribution.
E. e. erythrophris (Temminck, 1824) – N peninsula of Sulawesi.
E. e. centralis Riley, 1920 – NC & SE Sulawesi.
E. e. leptorhynchus Stresemann,1932 – C & S parts of C Sulawesi.
Descriptive notes. 27 cm. Medium-sized starling with tail strongly graduated, with long central rectrices. Has bright orange-red band of feathers from nares backwards over and behind eye, black

patch below and behind eye; rest of head and much of upperparts dark charcoal-grey, rump golden-yellow (feathers elongated); wing olive-green to olive-brown with olive-yellow margins on outer webs of remiges; tail brown, tinged with olive-yellow, terminal 2 cm of central rectrices cream; chin, throat, breast and belly dark charcoal-grey, thighs and undertail-coverts golden-yellow; iris pale yellow or sepia; bill black; legs sulphur-yellow. Sexes alike. Juvenile is browner than adult, with superciliary stripe narrower and yellower, iris brown. Race *centralis* has yellow superciliary stripe, and long, ridged bill; *leptorhynchus* is like nominate, with red eyebrow stripe, but has ridged bill. Voice. Song of male a monotonous, repetitive metallic "zeek zeek". Guttural calls as well as high-pitched "peep" from perched individuals; flight call "tik-tik".
Habitat. Rainforest in montane areas, also lowland and elfin moss forest; occasionally forest edge and selectively logged areas. Most numerous between 1000 m and 1500 m, but occurs up to 2300 m.
Food and Feeding. Omnivorous, diet primarily fruit and invertebrates. Berries and fruit collected in canopy and down to 1 m above ground. Insects gleaned in canopy, from epiphytes and from bark of tree trunks and branches; may hang upside-down while dislodging bark flakes. Forages in pairs, sometimes in trios; occasionally larger flocks, e.g. up to 55 individuals feeding at one time in fruiting fig tree (*Ficus*). At fruiting trees may associate with *Scissirostrum dubium* and *Basilornis celebensis*.
Breeding. No confirmed information. A photograph taken in Aug appears to show an individual of this species emerging from nest-hole with faecal sac, indicating presence of chicks.
Movements. Resident; probably locally nomadic in association with fruiting patterns of forest trees.
Status and Conservation. Not globally threatened. Restricted-range species: present in Sulawesi EBA. Generally common and fairly widespread, but somewhat local. Poorly known. Occurs in Dumoga Bone and Lore Lindu National Parks.
Bibliography. van den Berg & Bosman (1986), Blasius (1897), Coates & Bishop (1997), Riley & Mole (2001), Stresemann & Heinrich (1940b), Vorderman (1898a), Watling (1983), White & Bruce (1986).



Genus *SCISSIROSTRUM* Lafresnaye, 1845

18. Grosbeak Starling

Scissirostrum dubium

French: Scissirostre des Célèbes **German**: Finkenschnabelstar **Spanish**: Estornino Culipinto
Other common names: Celebes/Latham's Myna, Finch-billed Myna/Starling, Scissor-billed/Woodpecker Starling

Taxonomy. *Lanius dubius* Latham, 1801, locality unknown = Sulawesi.
Birds from Peleng described as race *pelingense*, but considered inseparable from those eslewhere in species' range. Monotypic.
Distribution. Sulawesi and nearby islands of Bangka, Lembeh, Togian Is, Buton, and Banggai Is (Peleng, Banggai).

Descriptive notes. 20 cm; 50 g. Smallish starling with massive bill. Plumage is mostly dark grey, darker on wing and tail; rump and uppertail-covert feathers, and some feathers on flanks, are elongated, with stiff, waxy tips which are bright red (sometimes faded to orange); iris very dark brown; bill and legs orange-yellow. Sexes alike. Juvenile is mouse-brown, with red or orange feather tips on rump, uppertail-coverts and flanks, iris blackish, bill slender and paler than that of adult, newly fledged individuals had yellow bill and pink legs. Voice. Song in courtship opens with chuckling notes, followed by loud whistles. Harsh rasping "schirr" calls, in flight a liquid "chiruip", nasal chatter, and repeated high-pitched "swee"; feeding groups gave whistled "wrriu"; soft chirruping from perched birds in aviary. Very noisy at colonies and in flocks; calls frequently in flight.
Habitat. Generally at forest edge and in lightly wooded areas; more common in modified habitats, and most frequently encountered in plantations. Relatively uncommon in primary forest and evidently absent in secondary forest. Sea-level to 1000 m, occasionally to 1100 m.
Food and Feeding. Diet fruit, seeds and insects; fruits taken include those of figs (*Ficus*) and *Albizzia*, and bird's-eye chilli (*Capsicum frutescens*). Spends most time in upper canopy; captives descend to ground infrequently for food or water. Highly gregarious; lives in medium-sized to large flocks of up to 150 individuals; forages often in association with *Aplonis minor*.
Breeding. Breeding recorded in May; captives nested in spring and summer in Europe. Monogamous. Colonial breeder, colonies containing up to hundreds of nests, pairs highly synchronized. Nest-hole bored in manner of woodpecker (Picidae) in dead wood in trunk more than 30 cm in diameter, at least 10 m above ground, cavity lined by both male and female with grass and leaves (nest-holes apparently utilized throughout year for roosting); large number of nests in same tree can weaken tree until it collapses; in captivity, pair used green leaves in courtship and in nest-building, and one captive pair lined a nestbox with thin strips of newspaper. Clutch 2 eggs, pale blue with brown speckles or reddish-brown patches concentrated at thicker end; in captivity two females each laid 2 eggs in same nest; incubation by both sexes, 13–14 days; chicks fed by both parents, apparently by regurgitation, nestling period 21–23 days; in captivity, adults continued to feed young for five weeks after fledging. Wild pairs apparently produced only one young per nest.
Movements. Resident; local movements for foraging purposes.
Status and Conservation. Not globally threatened. Widespread and common to locally very common. Breeds readily in captivity. Occurs in several protected areas, e.g. Dumoga Bone National Park.

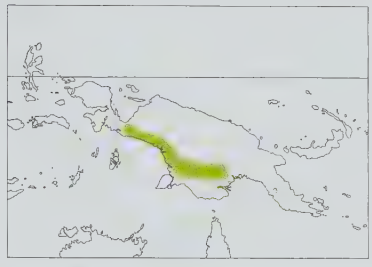
Genus *APLONIS* Gould, 1836

19. Shining Starling

Aplonis metallica

French: Stourne luisant **German**: Weberstar **Spanish**: Estornino Lustroso
Other common names: Metallic/Colonial Starling

Taxonomy. *Lamprotornis metallica* Temminck, 1824, "Timor and Celebes" = Ambon.
Genus name sometimes given as *Aplornis* (see page 659). Was previously thought to form a superspecies with *A. magna*. Five subspecies recognized.
Subspecies and Distribution.
A. m. metallica (Temminck, 1824) – Moluccas (including Sula Is), New Guinea and most satellite islands, Aru Is, and NE Australia (NE Queensland).
A. m. inornata (Salvadori, 1881) – Numfor and Biak, in N Geelvink Bay (NW New Guinea).
A. m. circumscripta (A. B. Meyer, 1884) – E Lesser Sundas (Damar and Tanimbar Is).
A. m. purpureiceps (Salvadori, 1878) – Admiralty Is (NW Bismarck Archipelago).
A. m. nitida (G. R. Gray, 1858) – Bismarck Archipelago (except NW) and Solomon Is.



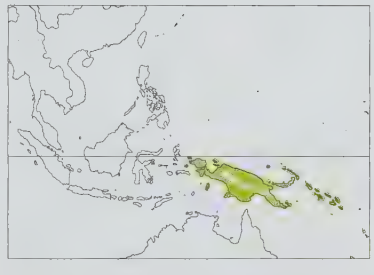
Descriptive notes. 25 cm; 48–67 g. Medium-sized starling with long graduated tail, and with long, lanceolate feathers on nape, and prominent red eye; black plumage with variable gloss. Nominate race has crown glossed purple, nape glossy satin-green with long, lanceolate feathers, mantle glossy purple, rump glossy emerald-green; wing brownish-black with some bluish iridescence, tail black with some gloss; throat glossy satin-green, upper breast glossy purple, lower breast and belly glossy emerald-green; iris red to orange-red; bill and legs black. Sexes alike. Juvenile is chocolate-brown above, wings blackish-brown with a little gloss, tail chocolate-brown, chin and throat buffy with brown shaft streaks, breast and belly brown with broad pale buff feather margins; iris dark brown, changing progressively through olive-yellow, yellowish-green and greenish-orange to adult colour. Race *circumstripta* is glossed reddish-purple on head, mantle and breast; *nitida* has bronze (rather than green) iridescence; *purpureiceps* is smaller and shorter-tailed, less glossy on head, and lacks purple on mantle; *inornata* is smaller and duller than nominate, lacking green on nape, having head, neck and mantle tinged purple, with almost no purple on upper breast. Voice. Song short and fluty in tone, described as being likae that of Island Canary (*Serinus canaria*); may include mimicry of other species, such as Hooded Pitta (*Pitta sordida*) and Common Koel (*Eudynamys scolopacea*). Flight call a descending nasal note; constant loud twittering at colonies, and returning individuals give high-pitched twittering call; also harsh and whistling calls, said to resemble those of congeners; harsh chattering heard from juveniles.
Habitat. Rainforest, coastal woodland, mangroves, also forest edge and clearings, gardens; visits fruiting trees in savanna. Usually below 1000 m, but recorded above 3000 m in E New Guinea.
Food and Feeding. Mainly frugivorous; also takes nectar, some insects. Fruits recorded as taken in Australia include those of native trees *Carallia brachiata*, *Myristica insipida*, *Schefflera actinophylla*, *Terminalia seriocarpa*, *Glochidion harveyanum*, *Glochidion ferdinandii*, *Polyscias elegans*, *Polyscias murrayi*, *Phycosperma elegans*, *Archontophoenis alexandrae*, *Scaevola koenigii*; also of exotic *Pinanga khulii* and *Capsicum frutescens*. Feeds on caterpillars (Lepidoptera); hawks flying ants and wasps (Hymenoptera) and mayflies (Ephemeroptera). Forages usually in small to large flocks of up to several hundred individuals, very occasionally in ones or twos; commonly associates with fruit doves (*Ptilinopus*), sometimes in mixed-species flocks with *A. mysolensis* (on Seram) and *A. mystacea* (in New Guinea). Roosts communally, performing complex aerial manoeuvres in flocks.
Breeding. In E New Guinea mostly Jul–Oct (Jul–Feb around Port Moresby), but Mar–May in some areas; Aug–Jan in NE Australia; apparently up to three successive broods at same colony, but not clear if same individual birds involved; captive pair in USA bred in all seasons. Presumed monogamous; possibly co-operative breeder at times, e.g. three adults working on one nest. Colonial breeder, with 4–400 nests often in single tree; adjoining nests can coalesce to form single structure. Domed nest with side entrance, made from twigs, vine tendrils and bark strips, lined with strips of palm frond and fresh green leaves, suspended 10–30 m above ground from ends of twigs in canopy. Clutch 1–4 eggs, pale blue, variably spotted and blotched with rufous and greyish-mauve markings; incubation possibly by female alone; chicks fed by both sexes, both by regurgitation and with food carried in bill; no information on duration of incubation and nestling periods.
Movements. Mainly resident or nomadic. Largely breeding visitor (mostly Jul–Feb/Mar) in NE Australia, spending non-breeding season in New Guinea; some may be present throughout year.
Status and Conservation. Not globally threatened. Common; abundant in many areas. In New Guinea, some colonies are treated as a traditional food source by humans, where certain individuals had the right to harvest nestlings; in Australia, likerwise, young were formerly collected for food by Aboriginals. This species features less in the trade in wild birds than do other members of genus.
Bibliography. Amadon (1956), Banfield (1912), Beecher (1945), Beehler (1978b), Bell, H.L. (1984b, 1986), Bishop & Brickle (1999), Blaber (1990), Blakers *et al.* (1984), Bockheim & Congdon (2001), Cain & Galbraith (1956), Clapp (1987), Coates (1985, 1990), Coates & Bishop (1997), Draffan *et al.* (1983), Gilliard & LeCroy (1966), Hadden (2004), Hartert (1926), Higgins *et al.* (2006b), LeCroy (1981a), LeCroy *et al.* (1984), Madarász (1897), Magarry (1987), Mayr & Diamond (2001), Mees (1982), Meyer, A.B. (1884), Meyer, P.O. (1933), Ogilvie-Grant (1915), Pavey (1991), Rand (1942a), Rand & Gilliard (1967), Reilly (1988), Schodde (1977), Schodde & Mason (1999), Sticklen (1981), Stresemann (1912a, 1914), Vorderman (1898b), White & Bruce (1986).

20. Yellow-eyed Starling

Aplonis mystacea

French: Stourne de Grant **German**: Mimikastar **Spanish**: Estornino Ojigualdo

Taxonomy. *Calornis mystacea* Ogilvie-Grant, 1911, Parimau, Mimika River, New Guinea.
Genus name sometimes given as *Aplornis* (see page 659). Monotypic.
Distribution. Discontinuously in W & SC New Guinea.



Descriptive notes. 18 cm. Medium-sized starling with rather long, graduated tail; bristly forehead feathers forming partly erectile crest (visible in field), and feathers of crown, nape, throat and upper breast elongated and lanceolate. Plumage is mostly black, glossed purple on head and mantle, glossed emerald-green on rump and wing-coverts, and glossed bronzy green on breast, belly and flanks; flight-feathers dark brown, some gloss on outer webs, tail dark brown and slightly glossy; iris pale yellow; bill and legs black. Sexes alike. Juvenile undescribed. Voice. Calls include harsh and bell-like notes; not properly distinguished from *Aplonis metallica* in most descriptions. High-pitched chattering at breeding colony.
Habitat. Forest, primarily lowland alluvial forest; reported also in hill forest to at least 300 m.
Food and Feeding. Diet presumably mainly fruit; red berries fed to young. Forages in canopy of lowland-forest trees such as *Endospermum moluccanum*. Generally in small groups, sometimes in larger flocks of up to c. 100 individuals; often in mixed flocks with *A. metallica*.
Breeding. Season apparently not documented. Colonial. One colony known, contained c. 150 nests: nest an untidy, mostly globular structure of strips of vegetation, suspended from or sometimes supported by branch, often in clusters of c. 15 nests, in forest tree c. 30 m tall. No other information.
Movements. Presumed resident; possibly nomadic.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Poorly known species, and status unclear because of close resemblance to *A. metallica*. Confirmed records from only a handful of localities: from R Wanggar and R Mimika in W, from middle R Turama and upper R Fly catchment, and, in SE, from R Nagore. Colonies sometimes destroyed by local human inhabitants, who collect adults, young and eggs for food.
Bibliography. Anon. (2008b), Beehler & Bino (1995), Butchart & Stattersfield (2004), Coates (1990), Feare & Craig (1998), Hartert *et al.* (1936), Ogilvie-Grant (1915), Rand (1938a), Rand & Gilliard (1967), Safford (1996), Stattersfield & Capper (2000).

21. Singing Starling

Aplonis cantoroides

French: Stourne chanteur **German**: Singstar **Spanish**: Estornino Cantor
Other common names: Little Starling

Taxonomy. *Calornis cantoroides* G. R. Gray, 1862, Misool, West Papuan Islands.
Genus name sometimes given as *Aplornis* (see page 659). May form a superspecies with *A. crassa*. Monotypic.
Distribution. West Papuan Is, New Guinea and some satellite islands, Aru Is, Bismarck Archipelago and Solomon Is.

Descriptive notes. 18 cm; 50–62 g. Medium-sized starling with bristly forehead feathers, and with feathers of crown and, particularly, throat hackled. Plumage is black with strong green iridescence, wing and tail black with some iridescence; iris red or orange; bill and legs black. Sexes alike. Juvenile differs from adult in having crown and upperparts dark brown with some green gloss, throat hackles pale buff with dark brown shafts, breast and belly feathers dark-centred with buff margins, broader buff area towards vent, brown iris. Voice. Song a short melodious whistle. Flight call a rustling sound resembling call of White-bellied Cuckoo-shrike (*Coracina papuensis*); creaking notes during foraging, and "pee wee" by feeding juveniles; "tiu tiu" call by adults at nest; other common calls are a repeated rising "su weii" and downward-inflected "siiew".
Habitat. In New Guinea found in wide range of natural and modified habitats, including urban areas; mainly in lowlands, up to 1700 m in mountain valleys. Primarily in forest on some islands.
Food and Feeding. Fruit, also insects. Fruits taken include figs (*Ficus*), fruit from forest palms, papaya (*Carica papaya*) and bird's-eye chilli (*Capsicum frutescens*). Hawks flying insects. Forages in pairs and small flocks, immatures also in large flocks; often feeds in association with *A. metallica*.
Breeding. Determination of season difficult owing to presence of individuals around nesting areas through much of year; recorded Sept–Feb in New Guinea (Sept–Dec around Port Moresby), and in Mar and Aug on smaller islands. Presumed monogamous. Sometimes breeds colonially. Nest in hole, usually in dead or living tree, sometimes in cliff, coral rock, or building or other man-made structure, lining material includes grass and plant fibres; sometimes occupies same trees as those used by *A. metallica*. Clutch 2–3 eggs, pale blue, spotted with brown and violet. No other information.
Movements. Increased abundance in New Guinea highlands during Apr–Nov suggests possible altitudinal migration. Flocks of juveniles may be nomadic; lack of geographical differentiation in populations also implies regular interchange between areas.
Status and Conservation. Not globally threatened. Widespread and common in New Guinea, as well as in several island groups. Reportedly extending its range into cultivated areas and colonizing some towns in montane areas.
Bibliography. Beecher (1945), Blaber (1990), Bradley & Wolff (1956), Cain & Galbraith (1956), Carter *et al.* (1997), Coates (1990), Diamond (1972), Finch (1986), Hadden (1981, 2004), Hartert (1926), Heinroth (1903), Higgins *et al.* (2006b), Hunter (1996), LeCroy (1981a), Mayr (1942), Mayr & Diamond (2001), Meyer (1929, 1933), Mitchell (1988), Rand & Gilliard (1967), Roberts (1996) Schodde (1977).

On following pages: 22. Tanimbar Starling (*Aplonis crassa*); 23. Atoll Starling (*Aplonis feadensis*); 24. Rennell Starling (*Aplonis insularis*); 25. Long-tailed Starling (*Aplonis magna*); 26. White-eyed Starling (*Aplonis brunneicapillus*); 27. Brown-winged Starling (*Aplonis grandis*); 28. Makira Starling (*Aplonis dichroa*); 29. Rusty-winged Starling (*Aplonis zelandica*); 30. Striated Starling (*Aplonis striata*); 31. Mountain Starling (*Aplonis santovestris*); 32. Asian Glossy Starling (*Aplonis panayensis*); 33. Moluccan Starling (*Aplonis mysolensis*); 34. Short-tailed Starling (*Aplonis minor*); 35. Micronesian Starling (*Aplonis opaca*); 36. Pohnpei Starling (*Aplonis pelzelni*).

22. Tanimbar Starling

Aplonis crassa

French: Stourne des Tanimbar **German**: Tanimbarstar **Spanish**: Estornino de las Tanimbar

Taxonomy. *Calornis crassa* P. L. Sclater, 1883, Larat, Tanimbar Islands.
Genus name sometimes given as *Aplornis* (see page 659). May form a superspecies with *A. cantoroides*. Monotypic.
Distribution. Tanimbar Is, in extreme E Lesser Sundas.

Descriptive notes. 20 cm. Medium-sized starling with comparatively sturdy bill, and with lanceolate feathers on crown and throat. Head and body are dark charcoal-black glossed with metallic green, slightly paler and less glossy ventrally; wing and tail dark brown with little gloss; iris dark brown; bill and legs black. Sexes alike. Juvenile is mousy brown above, with some greenish gloss on head, buff below, with dark shafts of throat feathers, and dark feather centres on breast and belly producing heavy streaking. Voice. Cacophony of piping, metallic calls from flocks; similar calls repeated at intervals by individual birds.
Habitat. Wooded areas, including secondary forest and woodland edge, and mangroves.
Food and Feeding. Diet fruit, probably also insects and nectar. Forages in dense crowns of flowering and fruiting trees. Forages singly, in pairs or in small groups, also in flocks of up to c. 200 individuals.
Breeding. No published information.
Movements. Presumed to be resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Banda Sea Islands EBA. Locally common in suitable habitat; has very small global range, and is vulnerable to habitat change. Heavy logging taking place in S part of Yamdena I, but it is tolerant of secondary and edge habitats. Protection of areas of suitable habitat recommended.
Bibliography. Anon. (2008b), Bishop & Brickle (1999), Butchart & Stattersfield (2004), Coates & Bishop (1997), Feare & Craig (1998), Stattersfield & Capper (2000), White & Bruce (1986).

23. Atoll Starling

Aplonis feadensis

French: Stourne des Fead **German**: Atollstar **Spanish**: Estornino de los Atolones
Other common names: Fead Island Starling

Taxonomy. *Calornis* (*Aplonis*) *feadensis* E. P. Ramsay, 1882, Fead, Nuguria Islands, east of Bismarck Archipelago.
Genus name sometimes given as *Aplornis* (see page 659). May form a superspecies with *A. insularis*; formerly considered conspecific, but is structurally and vocally distinct. Two subspecies recognized.
Subspecies and Distribution.
A. f. heureka Meise, 1929 – Ninigo Group, Hermit Is and Tench I (St Matthias Group), off NW & N Bismarck Archipelago.
A. f. feadensis (E. P. Ramsay, 1882) – Nissan I and Nuguria Is (E of New Ireland), Mortlocks and Carterets (E of Bougainville), and Ontong Java Atoll (N Solomon Is).

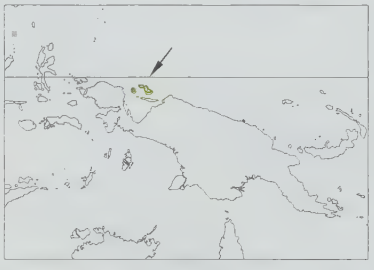
Descriptive notes. 20 cm; 72 g. Medium-sized starling with forehead feathers slightly bristly. Head and body are black, glossed with turquoise-green, wing and tail brownish-black with some gloss; iris yellow or dark yellow (one description suggests dark iris with pale yellow eyering); bill and legs black. Sexes alike. Juvenile lacks gloss on upperparts, has pale feather edges on underparts giving scaly effect, iris blue, becoming green. Races differ minimally: *heureka* has thinner bill and longer tail than nominate. Voice. Commonest call a loud ascending "weee-eeee"; softer calls resemble those of white-eyes (*Zosterops*). Song a rapid jumble of notes.
Habitat. Forest, forest edge and coconut (*Cocos nucifera*) groves; often found around gardens near forest, and readily enters gardens to exploit fruit trees.
Food and Feeding. Diet berries and insects. Forages in canopy; also at lower levels at forest edge, where sometimes descends to ground to feed. Gleans insects from leaves. In pairs or small flocks.
Breeding. Breeds Jun–Jul (young in nest). Nest in hole 5–10 m above ground in old tree or coconut stump. Clutch 2 eggs, pale blue, with reddish brown spots concentrated at thicker end; both adults seen to feed young. No other information.
Movements. Presumed resident, although individual seen flying between islands in Ninigo Group.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in New Britain and New Ireland EBA and in Ontong Java Atoll Secondary Area. Fairly common, but small population with total area of distribution probably no more than c. 64 km², spread over many small islets. Day counts on Tench of c. 30 individuals in 1998 and 15 in 1999; day counts of c. 30 on Nissan in 1998. Main potential threats are natural events such as cyclone damage and colonization of islands by *A. cantoroides*, compounded by continued habitat modification. With the exception of Nissan (37 km²), all islands inhabited by present species are tiny (less than 10 km² in surface area), and the small and fragmented forested habitats remaining on them are subject to high human population pressure; large areas already cleared for agriculture and coconut plantations. The species' apparent dependence on holes for nesting may be a limiting factor. In addition, as most of the islands which it inhabits are low (reaching only a few metres above sea-level), it is potentially at risk from climate change.
Bibliography. Anon. (2008b), Bayliss-Smith (1972), Bell (1975), Bradley & Wolff (1956), Butchart & Stattersfield (2004), Coates (1990), Dutson (2008b), Feare & Craig (1998), Finch (1986), Hadden (1981, 2004), Mayr & Diamond (2001), Stattersfield & Capper (2000).

24. Rennell Starling

Aplonis insularis

French: Stourne de Rennell **German**: Rennellstar **Spanish**: Estornino de la Rennell

Taxonomy. *Aplonis insularis* Mayr, 1931, Rennell, Solomon Islands.
Genus name sometimes given as *Aplornis* (see page 659). May form a superspecies with *A. feadensis*; formerly considered conspecific, but is structurally and vocally distinct. Monotypic.
Distribution. Rennell, in S Solomon Is.



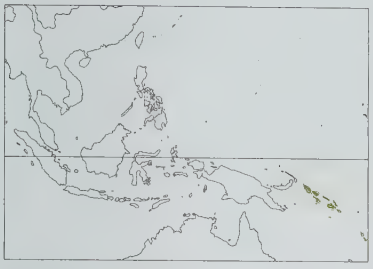
Descriptive notes. 19 cm; 66–74 g. Medium-sized, short-tailed starling with lanceolate throat feathers. Head and body are black, feathers of head, mantle, rump, throat and breast edged glossy blue-purple, belly and undertail-coverts matt black; wing and tail dark brown; iris yellow or orange-yellow; bill and legs black. Sexes alike. Juvenile is uniformly rich chocolate-brown, with slight metallic sheen on head produced by narrow glossy edges of feathers, iris brownish-grey, legs dark grey. Voice. Song a musical series of varied metallic notes, resembling those of *A. cantoroides* but less melodic. Flight call a sharp, metallic "chink".
Habitat. Forest edge, less often in forest and gardens.
Food and Feeding. Little information. Fruit, including figs (*Ficus*) and larger fruits such as papaya (*Carica papaya*); also insects and land snails (Gastropoda). Forages mostly in canopy, also descending to lower levels to feed in low shrubs and on ground. Shells of snails broken by being hammered against an "anvil". Observed generally in pairs.
Breeding. Nest in stump of coconut palm (*Cocos nucifera*) or hole in decayed tree; only clutch known was of 3 eggs, pale blue-green with red-brown blotches at the thicker end. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Rennell and Bellona EBA. Uncommon, but status not well known. Range tiny, so species potentially vulnerable.
Bibliography. Bradley & Wolff (1956), Diamond (1991), Dutson (2008b), Feare & Craig (1998), Finch (1986), Mayr (1931a).

25. Long-tailed Starling

Aplonis magna

French: Stourne à longue queue **German**: Biakstar **Spanish**: Estornino de la Biak

Taxonomy. *Lamprotornis magnus* Schlegel, 1871, Soëk, Misori (= Biak Island), New Guinea.
Genus name sometimes given as *Aplornis* (see page 659). Was previously thought to form a superspecies with *A. metallica*. Two subspecies recognized.
Subspecies and Distribution.
A. m. brevicauda (van Oort, 1908) – Numfor I, in NW Geelvink Bay (NW New Guinea).
A. m. magna (Schlegel, 1871) – Biak I, in N Geelvink Bay.



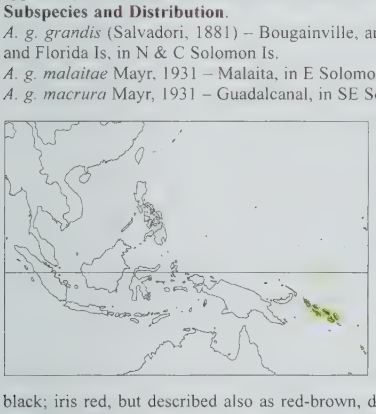
Descriptive notes. 28–41 cm (including tail). Large starling with long tail (central four feathers greatly elongated); forehead feathers bristly, feathers of crown and throat lanceolate. Nominate race has head and body black, glossed oily green, bronze gloss on head; remiges blackish-brown; tail as long as or longer than body, dark brown; iris brown; bill and legs black. Sexes alike. Juvenile undescribed. Race *brevicauda* is less glossy than nominate and has much shorter tail, about two-thirds of body length. Voice. Series of loud warbles; call a shrill slurred "cheeuw" on descending scale.
Habitat. Forest, secondary woodland, forest edge and gardens, at all altitudes.
Food and Feeding. Fruit. Forages in trees and undergrowth. Occurs in pairs and in small groups.
Breeding. Nest high up in tree. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Geelvink Islands EBA. Tiny global range, consisting of two islands. Reported as abundant on both islands.
Bibliography. Beehler *et al.* (1986), Coates (1990), Feare & Craig (1998), Harrison & Greensmith (1993), Rand & Gilliard (1967).

26. White-eyed Starling

Aplonis brunneicapillus

French: Stourne aux yeux blancs **German**: Weißaugenstar **Spanish**: Estornino Ojiblanco

Taxonomy. *Rhinopsar brunneicapillus* Danis, 1938, Buin, Bougainville.
Genus name sometimes given as *Aplornis* (see page 659). Monotypic.
Distribution. Bougainville, Choiseul, Rendova and Guadalcanal, in Solomon Is.
Descriptive notes. 23 cm; 59–77 g. Medium-sized, pale-eyed starling with small frontal crest formed by degenerate feathers of forehead, deep bill with strongly curved upper mandible, elongated crown and throat feathers; two central tail feathers greatly elongated. Male has black plumage with crown glossed bronze, lores purple-bronze, chin and throat iridescent purple, moustachial stripe emerald-green; mantle, upperwing-coverts, rump, breast and belly iridescent emerald-green; primaries and secondaries blackish-brown, purple gloss on outer webs; tail glossy black, central feather pair up to three times the length of outer rectrices; iris white; bill and legs black. Female is like male but slightly less iridescent, with elongated central rectrices shorter. Juvenile lacks frontal crest and tail extensions, has crown and nape dark purplish, mantle and rump glossed green, wings and tail glossed blue, underparts blackish-brown with some green feathers tips, white streaking on breast and centre of belly, iris olive to dark brown, bill less arched; bill initially grey, becoming black in older immatures. Voice. Calls described at nesting colony include "chreep" in courtship,



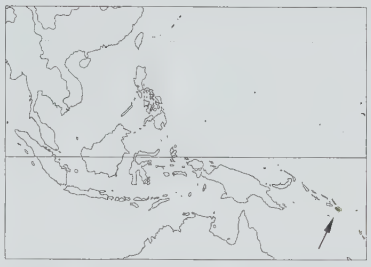
and whistled "kah kwik-kwik-kwik-kwik-chu-er" sequence (possibly song) during display at nest; harsh "kwaik" in alarm and "chk chk" chatter in aggressive encounters; whistled "kwee kwee chee-er" in flight by birds when returning to colony.
Habitat. Forest, including both lowland forest and hill forest to at least 800 m, and swamp-forest, also forest edge and second growth; also gardens, and trees in clearings.
Food and Feeding. Diet mainly fruit, including figs (*Ficus*), and fruits with large stones (which are presumably regurgitated). Forages mostly in canopy; also down to lower levels in gardens and around clearings. Generally in small flocks.
Breeding. Recorded in Jan on Bougainville and Jul–Aug on Guadalcanal. Presumed monogamous. Colonial; colonies of 10–40 nests in isolated trees. Nest consists of short horizontal tunnel, lined with moss, built among epiphytes on branches in canopy of tree. Eggs whitish, speckled with grey and chocolate-brown. Adults seen to carry food in bill to nestlings; latter preyed on by Pied Goshawk (*Accipiter albogularis*). No other information.
Movements. Presumed resident.
Status and Conservation. ENDANGERED. Restricted-range species: present in Solomon Group EBA. Rare and patchily distributed, with few recent records; poorly known. Total population estimated at fewer than 2500 individuals and believed declining. On Bougainville, single specimens taken in 1938 and 1944; colony of at least ten pairs in 1985, but not found two years later. Recorded at a single locality on Choiseul in 1994. On Rendova, one specimen taken in 1943 and records of two individuals in 1980s and some in 1990s. On Guadalcanal, 41 specimens collected in 1953 at Betilonga (in WC of island), but the species appears now to be extirpated there; a few recent records at Komarindi (in NW) and at Mt Austen (in N). Deforestation is increasing in Solomons, and most lowland forest and much hill forest throughout the species' range has been or is scheduled to be logged. No significant protected areas within its range; Mt Austen lies within the Queen Elizabeth National Park, but this is unprotected and highly degraded. In the past, local human inhabitants harvested nestlings for food, and this practice may continue.
Bibliography. Amadon (1956), Anon. (2008b), Beecher (1945), Butchart & Stattersfield (2004), Cain & Galbraith (1956), Coates (1990), David & Gosselin (2002a), Finch (1985, 1986), Gibbs (1996), Hadden (2004), Kaestner (1987), Mayr & Diamond (2001), Stattersfield & Capper (2000).

27. Brown-winged Starling

Aplonis grandis

French: Stourne des Salomon **German**: Kragenstar **Spanish**: Estornino de las Salomón
Other common names: Large Glossy Starling

Taxonomy. *Lamprocorax grandis* Salvadori, 1881, Santa Isabel, Solomon Islands.
Genus name sometimes given as *Aplornis* (see page 659). May form a superspecies with *A. dichroa*; formerly regarded as conspecific, but differs in size, morphology and plumage. Race *malaitae* may constitute a separate species, differing in morphology (smaller size, shorter tail, slimmer structure), white (or very pale blue) iris, distinct green gloss on head and body, shorter neck hackles, and apparently voice (some territorial calls); further study required. Three subspecies recognized.
Subspecies and Distribution.
A. g. grandis (Salvadori, 1881) – Bougainville, and Choiseul, Santa Isabel, New Georgia Group and Florida Is, in N & C Solomon Is.
A. g. malaitae Mayr, 1931 – Malaita, in E Solomons.
A. g. macrura Mayr, 1931 – Guadalcanal, in SE Solomons.



Descriptive notes. 27 cm; 110–151 g. Large starling with medium-length tail, bristly forehead feathers, and greatly elongated lanceolate feathers on crown, nape, throat and upper breast. Nominate race has mostly black plumage, crown to nape, throat and upper breast iridescent purple; mantle glossy green, passing into turquoise-purple iridescence on rump, upperwing coverts glossed bluish-purple; breast oily green, belly, flanks and undertail-coverts glossy bluish-purple; primaries and secondaries dark brown with some iridescence on outer webs, worn feathers paler brown (forming distinct wing patch in flight); tail dark brownish-black; iris red, but described also as red-brown, dark brown or grey-brown (possibly age-related changes); bill and legs black. Sexes alike. Juvenile is generally duller than adult, with lanceolate feathers less elongate, primares duller brown. Race *macrura* is like nominate but with much longer tail, particularly in male; *malaitae* is slimmer, with shorter head and throat hackles, distinct green gloss, whitish iris. VOICE. Song a continuous medley of warbles, chips, squeaks and shrill chattering notes, some at very high frequency; reminiscent of *Sturnus vulgaris* according to some observers. Deep, musical "pink pink"call during foraging; a guttural chirp and click may be contact calls; loud "chik" or "tip" in flight; also high-pitched repeated "hiiew". Loud fanning wing noise in flight.
Habitat. Forest; also secondary vegetation and cleared areas, including villages where some tall trees remain. Generally below 750 m, but on Guadalcanal from sea-level to 1200 m.
Food and Feeding. Fruit; also some insects. Takes pieces from large fruits such as figs (*Ficus*); fruit of *Cananga odorata* noted in diet. Forages high in trees. Usually seen singly or in pairs; occasionally in small flocks on Guadalcanal.
Breeding. May–Sept on Bougainville and Sept–Nov on Kolombangara, and extended season likely; single-brooded. Presumed monogamous; solitary nester. Nest a free-standing bulky mass of twigs, dry leaves, moss and grass, with side entrance, built in fork of tree or in cavity at end of broken branch. Clutch 2–3 eggs, pale green or blue with large brown spots, sometimes coalescing at thicker end. No further information.
Movements. Resident; observed while crossing open sea between islands 2 km apart.
Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Common on most islands in range, and occupies both primary forest and man-modified areas. Not thought to be at any risk, at least in near future.
Bibliography. Baker (1948), Blaber (1990), Cain & Galbraith (1956), Coates (1990), Diamond (2002), Dutson (2008b), Finch (1986), Hadden (1981, 2004), Mayr (1931b), Mayr & Diamond (2001), Schodde (1977).

28. Makira Starling

Aplonis dichroa

French: Stourne de San Cristobal **Spanish**: Estornino de San Cristóbal
German: San-Cristobal-Star
Other common names: San Cristobal Starling

Taxonomy. *Calornis dichroa* Tristram, 1895, San Cristobal, Solomon Islands.
Genus name sometimes given as *Aplornis* (see page 659). May form a superspecies with *A. grandis*; formerly regarded as conspecific, but differs in size, morphology and plumage. Monotypic.
Distribution. San Cristobal (Makira), in SE Solomon Is.

Descriptive notes. 20 cm; 73–92 g. Rather small starling with bristly forehead feathers and lanceolate feathers on crown, throat and upper breast. Plumage mostly blackish, with crown, throat and upper breast glossy purple-green, mantle and rump feathers dark brown with glossy bottle-green tips, upperwing-coverts blackish-brown with some gloss; belly and undertail-coverts matt blackish-brown; remiges tawny-brown and unglossed, appearing paler and browner than rest of plumage (especially when worn); tail dark brown; iris red, also orange or tawny (perhaps age-related); bill and legs black. Sexes alike. Juvenile browner and less glossy, with clear contrast between remiges and rest of plumage, iris tawny-orange. VOICE. Song soft and varied, repeated series of upslurred and downslurred notes. Highly vocal, calls include melodious whistles e.g. "wu-ee wu-ee tee" and "te-eu te-eu", a rising whistle, high-pitched squeaks and clicks, soft musical chattering, and harsh "chu-ai". Vocalizations similar to those of three local passerines: San Cristobal Cicadabird (*Coracina salomonis*), Long-tailed Triller (*Lalage leucopyga*) and local race *megarhynchus* of Chestnut-bellied Monarch (*Monarcha castaneiventris*).
Habitat. Forest, especially secondary forest, at all altitudes, but least common on coast; occasionally in more open habitats.
Food and Feeding. Fruit, mostly tiny fruits 1–2 mm in diameter; also seeds. Forages in outer twigs, primarily in canopy; hangs by feet in order to reach food items. Often in small groups of 3–8 individuals; sometimes in larger flocks of up to 30 birds.
Breeding. Monogamous. Builds solitary, compact spherical nest of sticks in dense forest subcanopy. Eggs reportedly whitish, sparingly marked with pale brown flecks. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Fairly common to locally common. Potentially vulnerable, as restricted to single island.
Bibliography. Cain & Galbraith (1956), Coates (1990), Diamond (2002), Dutson (2008b), Feare & Craig (1998), Finch (1986), Mayr & Diamond (2001).

29. Rusty-winged Starling

Aplonis zelandica

French: Stourne mélanésien **German**: Rostflügelstar **Spanish**: Estornino de Melanesia
Other common names: Rufous-winged/New Hebrides Starling

Taxonomy. *Lamprotornis zelandicus* Quoy and Gaimard, 1830, Tasman Bay, New Zealand; error = Vanikoro Island. Genus name sometimes given as *Aplornis* (see page 659). Three subspecies recognized.
Subspecies and Distribution.
A. z. maxwellii H. O. Forbes, 1900 – Nendo (Santa Cruz), in WC Santa Cruz Is.
A. z. zelandica (Quoy & Gaimard, 1830) – Vanikoro, in S Santa Cruz Is.
A. z. rufipennis E. L. Layard, 1881 – Banks Is and N & C Vanuatu (S to Efaté).

Descriptive notes. 19 cm. Rather small, dull-plumaged starling. Male nominate race has forehead, crown and nape dark brown with paler, olive edges; mantle and back brown, greenish gloss on back in fresh plumage, rump and uppertail-coverts tawny; wing dark brown, chestnut patch formed by outer webs of secondaries and eight inner primaries; tail brown; chin, throat, breast, belly and vent buffy grey-brown, flanks and undertail-coverts more chestnut in colour; iris pale brown; bill black; legs light brown. Female is similar to male, but smaller and paler. Juvenile undescribed. Race *rufipennis* is larger than nominate, plumage more buffy, with paler chestnut wing patch, rusty flanks and orange undertail-coverts; *maxwellii* is similar to previous, but browner below, with rufous undertail-coverts, also bill heavier and dark brown. VOICE. Most common call a short, melodious "zee-twee"; also repeated metallic whistles. Song short irregular phrases of clicks and metallic whistles.
Habitat. Forest; also secondary growth and partly cleared areas, including wooded gardens. On mountainous islands found primarily in montane forest.
Food and Feeding. Diet primarily fruit; also gleans insects from foliage. Forages mostly in lower canopy, sometimes lower. Generally singly or in pairs.
Breeding. Reported as nesting in tree hole high above ground. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Vanuatu and Temotu EBA. Poorly known species. Generally uncommon to scarce. Lowland and hill forests in this species' range potentially at risk from logging.
Bibliography. Anon. (2008b), Bregulla (1992), Butchart & Stattersfield (2004), Dutson (2008b), Feare & Craig (1998), Mayr (1942), Stattersfield & Capper (2000).

30. Striated Starling

Aplonis striata

French: Stourne calédonien **German**: Dickschnabelstar **Spanish**: Estornino de Nueva Caledonia

Taxonomy. *Coracias striata* J. F. Gmelin, 1788, New Caledonia.
Genus name sometimes given as *Aplornis* (see page 659). Two subspecies recognized.
Subspecies and Distribution.
A. s. striata (J. F. Gmelin, 1788) – New Caledonia.
A. s. atronitens G. R. Gray, 1859 – Loyalty Is.

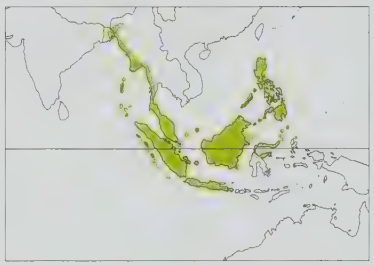
Descriptive notes. 18 cm; 49·5–60 g. Rather small blackish starling with short square-ended tail. Male nominate race has forehead and crown blackish, glossed violet and green; mantle, back and rump blackish-brown, feathers tipped with turquoise-green; flight-feathers and tail dark brown, outer webs of feathers slightly glossy; chin and throat feathers have green iridescence, breast and belly feathers tipped turquoise-green, lower belly and undertail-coverts matt black; iris orange-reddish; bill black; legs metallic blue. Female is smaller than male, with plumage uniformly mousy grey-brown, slightly paler below, iris reddish. Immature is similar to female. Race *atronitens* is larger and heavier-billed than nominate, male with greenish iridescence on head. Voice. Noisy. Loud clear thin whistles, e.g. "zhe" or "clee", often sharper and more metallic in flight; clear "chew-wee". Rushed warbling song with clear clicks, squeaks and fluid warbles.
Habitat. Forested areas, including forest edge and clearings, and savanna and gardens; also nearby coconut (*Cocos nucifera*) plantations and second growth; also in villages.
Food and Feeding. Reported food includes papaya (*Carica papaya*), small wild tomatoes (*Solanum lycopersicum*), peppers (*Capsicum*), berries, also insects; and land snails (Gastropoda), shells of which are broken by being hammered against an "anvil".
Breeding. Reported as nesting from Dec to Jan, building platform of twigs and leaves inside hole 1·5–25 m (average 10·5 m) above ground in hollow tree. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in New Caledonia EBA. Common and widespread within its tiny global range.
Bibliography. Barré & Dutson (2000), Barré *et al.* (2006), Doughty *et al.* (1999), Feare & Craig (1998), Finsch (1876a), Hannecart & Létocart (1983).

31. **Mountain Starling**

Aplonis santovestris

French: Stourne d'Espiritu Santo **German**: Rostbürzelstar **Spanish**: Estornino de Espíritu Santo
Other common names: Santo Starling

Taxonomy. *Aplonis santovestris* Harrisson and A. J. Marshall, 1937, Mount Watiamasan, Espiritu Santo, Vanuatu.
Genus name sometimes given as *Aplornis* (see page 659). Monotypic.
Distribution. Island of Espiritu Santo, in N Vanuatu.



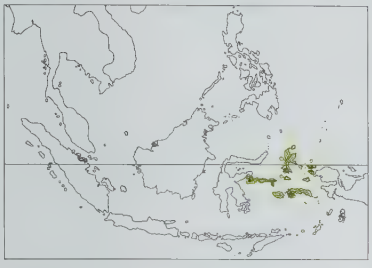
Descriptive notes. 18 cm. Male has forehead and crown dark brown, slight gloss on crown; upperparts, including upperwing-coverts, dark rusty brown, brighter on rump; primaries and secondaries dark brown with rusty outer webs; tail dark brown, rusty-brown margins on outer webs; throat brownish, underparts chestnut-brown; iris whitish; bill brownish-black, paler tip; legs light brown to flesh-coloured. Female is very like male, but has duller rufous plumage. Juvenile undescribed. Voice. Calls described include a hissing note and a harsh call; also "tzee-tzee-tzee" given from perch and in flight, apparently as contact call.
Habitat. Cloudforest above 1200 m.
Food and Feeding. Diet includes fruit, seeds and insects. Forages generally in understorey, below 6 m. Usually seen singly or in pairs.
Breeding. Reported as nesting in hole relatively low down in tree; clutch of 2 whitish eggs reported. No other published information.
Movements. Resident.
Status and Conservation. VULNERABLE. Restricted-range species: present in Vanuatu and Temotu EBA. Poorly known. Local people described the species as widespread in W mountains; in contrast, rarely encountered by visiting ornithologists, and known from very few localities. Recorded from three of the highest mountains (Mt Watiamasan, Mt Tabwemasana and Peak Santo) in, respectively, 1934, 1961 and 1991. No more than one pair has ever been seen, and several observers have failed to find the species. Introduced cats, dogs and rats (*Rattus*) now widespread.
Bibliography. Anon. (2008b), Bregulla (1992), Butchart & Stattersfield (2004), Collar *et al.* (1994), Feare & Craig (1998), Johannsen (1991), Reside (1991), Stattersfield & Capper (2000).

32. **Asian Glossy Starling**

Aplonis panayensis

French: Stourne bronzé **German**: Malaienstar **Spanish**: Estornino Bronceado
Other common names: Philippine (Glossy) Starling (*panayensis*); Indonesian Tree Starling (Indonesian races); Bornean Starling (*eustathis* and *alipodis*)

Taxonomy. *Muscicapa (panayensis)* Scopoli, 1786, nova Guiana; error = Philippines.
Genus name sometimes given as *Aplornis* (see page 659). Many races defined primarily according to size differences based on small samples, and require reassessment; some doubtfully distinct, e.g. *leptorrhyncha* perhaps better merged with *pachistorhina*. Fourteen subspecies currently recognized.
Subspecies and Distribution.
A. p. affinis (Blyth, 1846) – NE India (S Assam), Bangladesh and SW Myanmar.
A. p. tytleri (Hume, 1873) – Coco Is (off S Myanmar), Andaman Is, and N Nicobars (Car Nicobar).
A. p. albiris Abdulali, 1967 – C & S Nicobars.
A. p. strigata (Horsfield, 1821) – S Myanmar (Tenasserim), S Thailand, Peninsular Malaysia, Singapore, Sumatra (including most satellites), Java and W Borneo.
A. p. altirostris (Salvadori, 1887) – Simeluë, Banyak Is and Nias I (off NW Sumatra).
A. p. leptorrhyncha Stresemann, 1913 – Pini I, in N Batu Is (off W Sumatra).
A. p. pachistorhina (Oberholser, 1912) – Batu Is (except Pini) and Mentawai Is (off W Sumatra).
A. p. enganensis (Salvadori, 1892) – Enggano I, off SW Sumatra.
A. p. heterochlora (Oberholser, 1917) – Anamba Is and Natuna Is, between Malay Peninsula and Borneo.
A. p. panayensis (Scopoli, 1786) – Philippine Is and N Sulawesi.
A. p. sanghirensis (Salvadori, 1876) – Talaud Is and islands of Sangihe, Siau, Ruang, Tahulandang and Biaro (off NE tip of Sulawesi).
A. p. eustathis (Oberholser, 1926) – E Borneo.
A. p. alipodis (Oberholser, 1926) – Panjang, Maratau and Derawan, off E Borneo.
A. p. gusti Stresemann, 1913 – Bali.



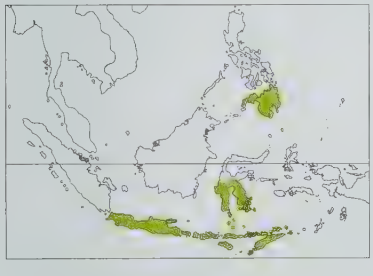
Descriptive notes. 20 cm; 50–60·5 g. Medium-sized starling with forehead feathers bristly and throat feathers lanceolate. Nominate race is black with greenish to oily gloss except on lowermost underparts, which are matt black; small black mask on lores and around eye; iris red; bill and legs black. Sexes alike. Juvenile is initially dark chocolate-brown above, with some green gloss on wings, whitish below with dark feather shafts, appearing heavily streaked, iris yellow, orange or pink; gloss develops progressively, and iris changes gradually to red. Race *sanghirensis* has more massive bill than nominate, and long frontal feathers form short crest; *alipodis* is duller and larger than nominate; *affinis* has stronger green gloss than nominate, crimson iris; *tytleri* is larger, darker and less glossy than previous, with gloss more bluish and iris often brown, though variable (reported also as pink and orange); *albiris* resembles last but has whitish iris; *strigata* is smaller than nominate with plumage showing a rather bluish- to blackish-green tinge on upperparts and more greenish gloss on underparts; *altirostris* differs from previous in having much heavier and distinctively arched bill, and duller plumage with less pure green, more purplish-bronze gloss; *leptorrhyncha* has very slender bill and pure blue gloss on plumage; *pachistorhina* is slightly larger than previous two races with larger, coarser bill, green gloss on plumage and less lanceolated feathers on neck; *heterochlora* is like *strigata* but much larger, heavier-billed, with plumage of adult more bronzy or oily green, but appears more grassy green than nominate; *eustathis* is extremely similar to *strigata*, but overall smaller; *enganensis* also similar to *strigata* but larger with longer wings and stronger bill, immature plumage apparently also different; *gusti* is small with short, weak bill, dorsal gloss much bluer, especially towards rear, and head feathers less elongated and lanceolated than in the adjacent Javanese population. Voice. Calls have a metallic quality; repeated "tsuu tsuu" call, also shrill "tseeu" and "tieuu" whistles, and descending "tseeeer"; high-pitched trill also given (e.g. at roost); flocks noisy. No reports of a vocalization corresponding to song.
Habitat. Forest, forest edge and clearings, secondary growth, mangroves and coastal vegetation, also gardens and coconut (*Cocos nucifera*) plantations; lowlands, generally below 700 m. Sometimes enters urban areas to roost, e.g. in Singapore. Communal roosts may contain up to 15,000 birds; roosts in association with *Acridotheres tristis* and *Acridotheres javanicus*.
Food and Feeding. Diet mainly fruit; also nectar, insects, spiders (Araneae), and snails (*Hemiplecta*). Fruits recorded in diet include, among others, *Ficus fistulosa*, *Ficus grossalaroides*, *Pipturus argenteus*, *Homalanthus populnesu*, *Morinda citrifolia*, *Scaevola taccada*, *Tinospora glabra*, *Leucosyke capitellata*, *Cayratia trifolia*, *Dysoxlylum guadichaudianum*, *Endospermum malaccense*, *Fagraea fragrans*, *Eugenia polyanthus* and *Compnospermum auriculatum*; also exotic *Ptychosperma macarthurii*, nuts of *Caryota mitis*, arils of *Acacia auriculiformis*. Nectar taken from flowering trees of *Bombax* and *Erythrina*. Insects consumed include adult and larval beetles (of family Carabidae), caterpillars (Lepidoptera), mole-crickets (Gryllotalpidae), immature grasshoppers (Orthoptera). Mainly arboreal, foraging often in tops of trees; will eat fallen fruit on ground, and often descends to ground to capture insects; in Malay Peninsula seen to feed on large snails on ground, smashing them against hard objects to break the shells. Hawks alate termites (Isoptera) in air. Highly gregarious, feeding in flocks.
Breeding. Breeds Feb–Apr in NE India, Apr in Andamans and Nicobars, Mar–Jun in Myanmar, Jan–Aug in Peninsular Malaysia, Jan–Jun in Java and Bali, mainly Jun–Sept (some Jan–Oct) in Borneo, and Feb–Jun in Philippines. Presumed monogamous. Sometimes colonial breeder. Nest a rough cup of roots, grass and leaves, placed in natural cavity or old woodpecker (Picidae) hole in living or dead tree, in crown of palm tree, or in hole in cliff or bank, including hole excavated by kingfisher (Alcedinidae), sometimes in hollow in wall, under house eaves or in nestbox; occasionally among epiphytes on large tree. Clutch 3 eggs, blue or blue-green with brown spots; no information on incubation and nestling periods. Ringed individuals survived for at least 7 years.
Movements. Chiefly resident, with some local movements. Apparently a partial migrant in NE Indian Subcontinent, some leaving area after breeding. Some local movement can be extended and involve sea crossings. In Philippines, described as a "wanderer that borders on migratory"; on some islands a breeding visitor only. Dispersal may be over relatively long distances, and movement then sometimes nocturnal.
Status and Conservation. Not globally threatened. Widespread, and common to locally very common throughout most of extensive range. Despite hunting and trapping for food in Philippines, still common through most of the archipelago. Potentially an important agent in the dispersal of seeds of some trees; on the other hand, is common enough to be a pest of crops such as pepper in some areas. Recorded as a rare exotic escapee (race unknown) in Taiwan; breeding there unconfirmed.
Bibliography. Abdulali (1967), Ali & Ripley (1972), Amadon (1956), Blasius (1888, 1897), Choudhary (2004), Coates & Bishop (1997), Corlett & Lucas (1989), Delacour & Mayr (1946), Dickinson *et al.* (1991), Hails (1987), Hoogerwerf (1965a), Hoogerwerf & Rengers Hora Siccama (1938), Kang Nee (1989), Kennedy *et al.* (2000), Lin Rueyshing (2001), MacKinnon & Phillipps (1993), van Marle & Voous (1988), McClure (1998), Medway & Wells (1976), Mees (1986), Oberholser (1917b, 1919a, 1919b, 1932), Peh & Chong Fong Lin (2003), duPont (1971), Rand & Rabor (1960), Rasmussen & Anderton (2005b), Rensch (1930), Riley (1929), Robson (2000), Smythies (1960, 1986), Smythies & Davison (1999), Vorderman (1898a), Wells (2007), White & Bruce (1986), Whittaker & Jones (1994).

33. **Moluccan Starling**

Aplonis mysolensis

French: Stourne des Moluques **German**: Molukkenstar **Spanish**: Estornino Moluqueño
Other common names: Island Starling

Taxonomy. *Calornis mysolensis* G. R. Gray, 1862, Misool, West Papuan Islands.
Genus name sometimes given as *Aplornis* (see page 659). Geographical variation trivial; birds from from Banggai Is described as race *persimilis*, those from Sula Is as *sulaensis*, and those from Halmahera as *forsteni*, but all considered inseparable from birds of this species elsewhere in range. Treated as monotypic.
Distribution. Banggai Is and Sula Is, off E Sulawesi; Morotai, Halmahera, Ternate, Bacan, Obi, Buru, Seram, Ambon, Haruku and Saparua, in Moluccas; and West Papuan Is (Gebe, Ajoe, Waigeo, Batanta, Salawati, Misool, and some smaller islets).



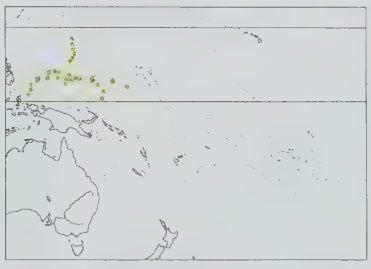
Descriptive notes. 20 cm. Medium-sized starling with fairly long, strongly graduated tail (central feather pair longest), bristly feathers on forehead, and lanceolate but not elongated feathers on neck and throat. Plumage is mostly black, glossed with green-purple; wings and tail duller; iris brown; bill and legs black. Sexes alike. Juvenile is shorter-tailed than adult, chocolate-brown above, feathers of underparts chocolate-brown with pale margins, producing heavily streaked appearance. Voice. High-pitched "teeck" calls during foraging; short "sqweow sqweow" in flight; also a wide variety of nasal whistles, chattering and squealing notes, as well as piercing, upward-inflected notes.
Habitat. Ranges from mangroves and coastal woodland to lowland forest, and to hill forest above 1000 m; also in degraded forest, cultivated areas, scrub, and trees in settlements and some towns.
Food and Feeding. Fruit; probably also insects and nectar. Noted in figs (*Ficus*), casuarinas (*Casuarina*) and flowering sago palms (*Metroxylon*). Forages generally in flocks, occasionally in pairs or singles, high in trees; may form mixed flocks with *A. metallica*.
Breeding. No information on season. Presumed monogamous. Colonial nester; colonies contain up to 50 individuals, occasionally more (up to 200 recorded). Nest in tree hole; said to excavate own hole in dead wood. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Fairly common in most of range; common on some islands; scarcer on Buru. Apparently tolerant of altered habitats.
Bibliography. Coates & Bishop (1997), Feare & Craig (1998), Jepson (1993), Rand & Gilliard (1967), Stresemann (1914), Vorderman (1898b), White & Bruce (1986).

34. Short-tailed Starling

Aplonis minor

French: Stourne à queue courte **German**: Sundastar **Spanish**: Estornino Colicorto
Other common names: Lesser/Short-tailed Glossy Starling

Taxonomy. *L[amprotornis] minor* Bonaparte, 1850, Timor.
Genus name sometimes given as *Aplornis* (see page 659). Birds from Mindanao sometimes separated as race *todayensis*; further study required. Treated as monotypic.
Distribution. S Philippines (Mindanao), C & S Sulawesi (and islands of S coasts), islands in Flores Sea (Tanahjampea, Kayuadi, Kaleo, Kaleotoa), Java, Bali and Lesser Sundas (E to Roma and Moa).



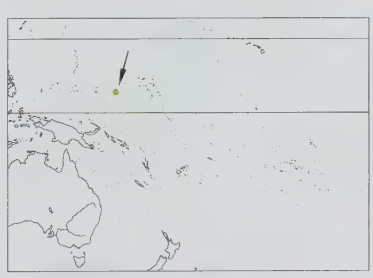
Descriptive notes. 18 cm; 39–45 g. Small starling with short tail. Plumage mostly blackish, head and neck iridescent bronzy purple, with brighter purple on nape, side of neck, throat and breast; body iridescent oily green; wing black, some green gloss on secondaries, tail black, with green gloss on outer rectrices; iris vermilion; bill and legs black. Sexes alike. Juvenile dark brown above, some green gloss on crown and back, brown below, paler on throat and belly, with paler margins of feathers producing streaked look. Voice. Plaintive "seep" as contact call; clear metallic shriek, "teek teek", in flight; short chattering notes and slurred, metallic "chilanc".
Habitat. Forest and forest edge; rarely in cultivated areas and villages in most of range, but in Java and Bali apparently favours cultivated areas close to forest. Generally in lowlands, below 1500 m; on Mindanao found in mountain forest above 900 m.
Food and Feeding. Fruit and berries, also insects; coffee (*Coffea*) berries reported as eaten. Forages both in forest canopy and at edge. Gregarious; forages in small flocks, forms communal roosts.
Breeding. Few data. Birds with enlarged gonads in Apr on Mindanao. Said to nest in tree holes in small colonies; other accounts imply that this species nests solitarily and excavates own hole in dead tree. Eggs reportedly blue-green with fine brown speckling.
Movements. Mostly resident. On some islands apparently present only seasonally, and may be nomadic or migratory; according to some authors, a non-breeding migrant in Java and Bali.
Status and Conservation. Not globally threatened. Widely distributed and locally common. Uncommon to locally moderately common in Wallacea.
Bibliography. Amadon (1956), Coates & Bishop (1997), Dickinson *et al.* (1991), Feare & Craig (1998), Kennedy *et al.* (2000), MacKinnon (1988), MacKinnon & Phillipps (1993), Meise (1929), Meyer (1884), duPont (1971), Rensch (1930, 1931), Trainor & Soares (2004), Vorderman (1895), White & Bruce (1986).

35. Micronesian Starling

Aplonis opaca

French: Stourne de Micronésie **German**: Karolinenstar **Spanish**: Estornino de Micronesia

Taxonomy. *Lamproth.* [*ornis*] *opaca* Kittlitz, 1833, Kosrae, Caroline Islands.
Genus name sometimes given as *Aplornis* (see page 659). Seven subspecies recognized.
Subspecies and Distribution.
A. o. aenea Takatsukasa & Yamashina, 1931 – N Northern Mariana Is (Asuncion, Agrihan, Pagan, Alamagan).
A. o. guami Momiyama, 1922 – S Northern Marianas (Saipan, Tinian, Rota, Guam).
A. o. orii Takatsukasa & Yamashina, 1931 – Palau Is (Kayangel, Babelthuap, Koror, Garakayo, Ngesebus, Peleliu, Ngabad, Angaur).
A. o. kurodai Momiyama, 1920 – Yap, in extreme W Caroline Is.
A. o. anga Momiyama, 1922 – Caroline Is (Ulithi, Fais, Faraulep, Woleai, Ifalik, Lamotrek, Chuuk, Lukunor, Nukuoro).
A. o. ponapensis Takatsukasa & Yamashina, 1931 – Pohnpei (including Kapingamarangi Atoll, 740 km SW of main island), in E Carolines.
A. o. opaca (Kittlitz, 1833) – Kosrae, in extreme E Carolines.



Descriptive notes. 24 cm; 71–93 g. Rather large starling with short tail. Nominate race is entirely black, with slight green iridescence on head, mantle, back and wing-coverts; iris yellow; bill and legs black. Sexes similar, female slightly smaller and duller than male. Juvenile has crown to rump, wings and tail dark brown without gloss, throat and breast dark brown with pale buff feather margins, producing heavily streaked appearance, broader pale margins on belly feathers; iris yellow from an early stage, bill initially horn-coloured at base. Races differ mainly in bill size and colour of gloss: *ponapensis* is larger than nominate, with longer bill, richer green iridescence; *anga* also is larger, with marked greenish iridescence both above and below; *kurodai* has heavier bill, bronzy-green gloss on plumage; *aenea* has smaller bill, bronze gloss; *guami* has shorter bill, green iridescence on entire plumage; *orii* is larger than nominate, with longer and more slender bill. Voice. Song, delivered from high perch, a melodious ascending phrase consisting of modified call notes. Calls varied, including whistles and gurgling notes, sometimes in chorus with other individuals, and a chipping call in flight; typical call described as harsh rolling "brleeep".
Habitat. Forest and disturbed areas, from coastal scrub to dense coconut (*Cocos*) forest, from sea-level to tops of mountains. Occurs in settlements, as well as on islands which are seldom visited by humans.
Food and Feeding. Diet primarily fruits and seeds; also insects, and eggs of seabirds; sometimes described as omnivorous. Fruits taken include those of figs (*Ficus*), papaya (*Carica papaya*) and *Pithecellobium dulce*. Insects found in stomach contents were a wasp (Hymenoptera), a grasshopper (Orthoptera) and unidentified larvae. Eggs of Black Noddy (*Anous minutus*) and Red-footed Booby (*Sula sula*) taken; may take advantage of human disturbance in seabird colonies to attack eggs. Otherwise, forages primarily in trees, both in understorey and in canopy. Often in flocks, generally of up to twelve individuals.
Breeding. Breeds in all months on Guam, in Aug on Yap and Pohnpei, and in Oct–Dec on Chuuk. Monogamous. Nest built from sticks, lined with grass and leaves, placed in cavity 4–15 m above ground in tree, palm or tree-fern, or sometimes in cliff or in rotting pole or other man-made structure. Clutch 1–4 eggs, generally 2, pale green or greenish-blue, spotted with black, brown, russet and purple, concentrated at thick end; incubation by both sexes, no information on duration; chicks fed by both parents, both also remove faecal sacs, nestling period 21–25 days; independent young join flocks of other juveniles.
Movements. Resident; populations tend to be distinct from those on other islands in same region, suggesting that little or no interchange occurs.
Status and Conservation. Not globally threatened. Restricted-range species: present in Mariana Islands EBA, in Palau EBA, in Yap Islands EBA and in East Caroline Islands EBA. Common in most of range. Found in varied habitats on even small islets; density on Kapingamarangi Atoll (Pohnpei) estimated at 5·7 birds/ha. Population on Guam devastated following introduction of brown tree-snake (*Boiga irregularis*), a major nest predator, which was established throughout the island by 1968; latest assessments indicate that it has lost more than 90% of its population since roadside surveys began, in 1974, and no signs of any recovery by 1998; this is, however, the only native passerine surviving on Guam, perhaps because it sometimes nests in buildings which are relatively clear of snakes. Collected for food on some islands.
Bibliography. Amadon (1956), Baker (1951), Brandt (1962), Buden (1998), Craig, R.J. (1996), Finsch (1876a), Fisher (1950), Jenkins (1983), Reichel & Glass (1990), Wiles *et al.* (2003).

36. Pohnpei Starling

Aplonis pelzelni

French: Stourne de Ponapé **German**: Pelzelnstar **Spanish**: Estornino de Ponapé
Other common names: Pohnpei Mountain Starling

Taxonomy. *Aplonis pelzelni* Finsch, 1876, Pohnpei, Caroline Islands.
Genus name sometimes given as *Aplornis* (see page 659). Monotypic.
Distribution. Pohnpei, in E Caroline Is.

Descriptive notes. 16 cm. Small dull starling lacking iridescence in plumage. Head and upperparts are sooty brown, paler brown on rump and uppertail-coverts; wing and tail also pale brown; throat and underparts pale brown, washed with olive-brown; iris brown; bill and legs black. Sexes alike. Juvenile is similar to adult but lighter brown, particularly on underparts. Voice. Call described as a shrill "see-ay" with bell-like quality.
Habitat. Forest in mountains, above c. 500 m; formerly more widespread and extending to lowlands.
Food and Feeding. Diet mainly fruits, also seeds and insects. Berries taken from shrubs; some insect food and seeds collected on ground. Normally forages in pairs.
Breeding. Female in breeding condition in Jul. Said to nest in tree hole and to lay 2 eggs; confirmation required. No other information.
Movements. Resident.
Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in East Caroline Islands EBA. This species was not found in a survey in 1983 and was thought to be extinct, until a specimen was obtained in 1995; also several unconfirmed reports. Has declined drastically; in 1930, over a three-month period, 60 specimens were collected. Habitat loss, hunting and possible predation by rats (*Rattus*) may account for decline.

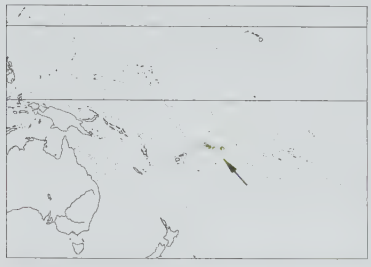
37. **Polynesian Starling**

Aplonis tabuensis

French: Stourne de Polynésie **German**: Südseestar **Spanish**: Estornino de Polinesia
Other common names: Striped Starling

Taxonomy. *Lanius tabuensis* J. F. Gmelin, 1788, Friendly Islands = Tonga Islands.
Genus name sometimes given as *Aplornis* (see page 659). Twelve subspecies recognized.
Subspecies and Distribution.
A. t. pachyrampha Mayr, 1942 – Tinakula Group and Swallow Is, in Santa Cruz Is.
A t. tucopiae Mayr, 1942 – Tikopia, in SE Santa Cruz Is.
A. t. rotumae Mayr, 1942 – Rotuma I (N of Fiji).
A. t. fortunae E. L. Layard, 1876 – Wallis and Futuna Is (Horne Is).
A. t. brevirostris (Peale, 1848) – Samoa.
A. t. tutuilae Mayr, 1942 – Tutuila I, in American Samoa.
A. t. manuae Mayr, 1942 – Manua Is, in American Samoa.
A. t. vitiensis E. L. Layard, 1876 – Fiji (except E).
A. t. nesiotes Mayr, 1942 – Niuafo'ou, in N Tonga.
A. t. tenebrosa Mayr, 1942 – Tafahi and Niuatoputapu, in N Tonga.
A. t. tabuensis (J. F. Gmelin 1788) – Lau Archipelago (E Fiji) and S Tonga Is.
A. t. brunnescens Sharpe, 1890 – Niue, E of Tonga.



Descriptive notes. 20 cm; 52–69 g. Medium-sized, stocky, rather short-tailed starling with relatively short bill and brown or brownish plumage. Nominate race is brown above, darker and with violet iridescence on forehead and crown; wing dark brown, paler margins on outer webs of secondaries (producing pale patch on closed wing); tail brown; paler buffy brown below, white feather shafts on throat and breast producing slight streaked effect; iris red-brown; bill dark horn-brown; legs dark brown. Sexes alike. Juvenile apparently undescribed. Race *brunnescens* has smaller, thinner bill than nominate, no iridescence on crown, iris red-brown or dark brown; *tenebrosa* is uniformly dark sooty brown, upperparts glossed greenish, underparts with buffy shaft streaks; *nesiotes* is darker than nominate (but not so dark as previous), and iris is yellow; *pachyrampha* has dark brown underparts, shaft streaks only on lower breast and flanks, iris brown; *tucopiae* is uniformly brown without streaking on underparts, gloss restricted to crown, iris brown or yellowish; *rotumae* duller than nominate, most of plumage with olivaceous tinge, has broad greyish margins on back and rump feathers, more white on lower belly, more slender and less curved bill, iris yellow; *fortunae* is somewhat smaller than nominate, with browner back and paler, more streaked underparts, iris yellow; *brevirostris* is smaller and darker than nominate, but with prominent streaking below, pale wing patch, stubby pale brown bill, iris yellow; *tutuilae* is larger than previous, with darker underparts, more distinct light shaft streaks and large bill, iris yellow; *manuae* has darker back than last, no wing patch, dark grey-brown underparts without streaks, small bill, iris yellow; *vitiensis* has thinner bill than nominate, more pronounced streaking on underparts, paler wing patch, iris colour varies from brown on N & W islands to yellow elsewhere in range. Voice. Dry buzzing rattle; advertising call a high-pitched double whistle, "twee-wee", repeated frequently; other whistles recorded, and a hissing call. Complex whisper song with mimicry.
Habitat. On smaller islands exploits all habitats, including highly disturbed areas such as regenerating scrub and coconut (*Cocos nucifera*) plantations; on larger islands primarily in forest, also in well-wooded secondary habitats. On islands where *A. atrifusca* occurs, present species found mainly in high forest.
Food and Feeding. Diet mainly fruit, also insects gleaned from foliage. On Niuafo'ou I (N Tonga), took fruit of *Morinda citrifolia*, *Cassytha filiformis*, *Scaevola frutescens* and *Premna taitensis*. Forages at all levels, from low scrub to high canopy, in active and often acrobatic fashion; observed clinging to tree trunks, supported by the tail in woodpecker (Picidae) style, while probing crevices in bark. Generally seen in small flocks, occasionally singly.
Breeding. Mar–Aug/Sept in Samoa; recorded in Aug on Niue. Nest built from dry vegetable fibres, at variable height in tree hole or broken stump of coconut palm; clutch 2–3 eggs, blue with brown and red-brown spots and blotches. No other information.
Movements. Apparently resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Vanuatu and Temotu EBA, in Fiji EBA, in Samoan Islands EBA, in Rotuma Secondary Area, in Wallis and Futuna Secondary Area, in Niuafo'ou Secondary Area, in Tonga Secondary Area and in Niue Secondary Area. Widely distributed over several groups of small islands; considered to be common on many of the islands in its range.
Bibliography. Beichle & Baumann (2003), Bellingham & Davis (1988), David & Gosselin (2002b), Kinsky & Yaldwyn (1981), Mayr (1942), Muse & Muse (1982), du Pont (1976), Rinke (1986, 1987), Watling (1982).

38. **Samoan Starling**

Aplonis atrifusca

French: Stourne de Samoa **German**: Samoastar **Spanish**: Estornino de Samoa

Taxonomy. *Lamprotornis atrifusca* Peale, 1848, Upolu, Samoa.
Genus name sometimes given as *Aplornis* (see page 659). Monotypic.
Distribution. Samoan Is, occurring in Samoa (Savai'i and Upolu) and American Samoa (Tutuila, Ofu, Olosega and Tau).
Descriptive notes. 30 cm; 125–158 g. Large starling with longish square-ended tail and strong bill. Forehead, crown and nape are dark brown with violet-green iridescence, mantle brown with greenish iridescence (on feather tips); rump, wing and tail sepia-brown, rufous tinge on outer webs of primaries forming indistinct panel; chin to upper breast blackish-brown with violet-green iridescence, belly medium brown with greenish iridescence; iris dark brown; bill and legs black. Sexes alike. Juvenile described as dull brown. Voice. Calls monosyllabic, include harsh screech and softer whistles, also rasping and squeaking notes. Loud wing noise in flight.

Habitat. Primarily coastal vegetation and plantations, also lower forests, especially when partially logged, and cultivations; least common in higher-lying forest, but occurs at all elevations. Commonly found around villages and towns.
Food and Feeding. Diet mainly fruit, especially guavas (*Psidium*), bananas (*Musa*) and papayas (*Carica papaya*); also invertebrates. Seen to probe flowers of *Erythrina*, presumably for nectar (has brush-like tongue). Forages mostly in tops of trees; in small flocks, also singly.
Breeding. Season probably at least Mar–Jul. Nest in hole in tree, one 10 m up in hole in top of coconut palm (*Cocos nucifera*). Eggs reported as pale blue. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Samoan Islands EBA. Common. Numbers on Tutuila fell by c. 66% in early 1990s following a hurricane. Considered an aggressive species towards introduced competitors. Sometimes considered an agricultural pest. In contrast, is an important pollinator of some Samoan plants, such as the liana *Freycinetia reineckei*. Exploited for food on some islands.
Bibliography. Beichle & Baumann (2003), Bellingham & Davis (1988), Cox (1982), Craig *et al.* (1994), Dhondt (1976), Evans, S.M. *et al.* (1992), Mayr (1942), Muse & Muse (1982), Watling (1982).

39. **Rarotonga Starling**

Aplonis cinerascens

French: Stourne de Rarotonga **German**: Rarotongastar **Spanish**: Estornino de Rarotonga

Taxonomy. *Aplonis cinerascens* Hartlaub and Finsch, 1871, Rarotonga.
Genus name sometimes given as *Aplornis* (see page 659). Monotypic.
Distribution. Rarotonga I, in S Cook Is.

Descriptive notes. 21 cm; 77–88 g. Medium-sized, greyish-brown starling. Forehead and crown are mousy brown with faint purple iridescence; mantle, back and rump mouse-brown, edged with grey; wing and tail dull brown, paler edges on inner secondaries; chin, throat, breast and upper belly mouse-brown, broad paler tips on breast and belly, lower belly and undertail-coverts whitish; iris pale yellow, sometimes dark brown with narrow yellow outer ring; bill and legs black. Sexes alike. Juvenile undescribed. Voice. Song sweet, described as the most melodious of any Rarotonga bird species. Calls include whistles, squeaks and bell-like notes.
Habitat. Undisturbed montane forest, also disturbed fringing forest, in rugged interior from 150 m to highest point of island (600 m). Sometimes lower, down to as low as 30 m, but much rarer in coastal areas than was previously the case.
Food and Feeding. Diet includes fruit and insects, also nectar. Feeds on fruit in canopy, also at flowers; gleans insects from foliage. Forages singly and in pairs.
Breeding. Season Aug–Dec. Nest a lining of dead leaves and plant fibres in tree hole 4–6 m above ground, with apparent preference for native trees (e.g. *Bischofia javanica*, *Homalium acuminatum* and *Hernandia moerenhoutiana*); nest-hole reused in subsequent years. Clutch at least 2 eggs. No other information.
Movements. Resident.
Status and Conservation. VULNERABLE. Restricted-range species: present in Southern Cook Islands EBA. Population currently thought to be stable. Considered abundant in 1904, and population of several thousands estimated in 1973, but by 1984 no more than c. 100 individuals; the most recent estimates are of c. 500 birds. Habitat destruction and introduced rats (*Rattus*) believed to be the main threats. Seems to have disappeared from lowlands in 1970s, possibly owing to aggressive competition from introduced *Acridotheres tristis*, which apparently has not penetrated forested uplands.
Bibliography. Anon. (2008b), Butchart & Stattersfield (2004), Collar & Andrew (1988), Collar *et al.* (1994), Feare & Craig (1998), Holyoak & Thibault (1984), Mayr (1942), McCormack (1997), Stattersfield & Capper (2000).

Genus *STURNUS* Linnaeus, 1758

40. **Common Starling**

Sturnus vulgaris

French: Étourneau sansonnet **German**: Star **Spanish**: Estornino Pinto
Other common names: European/Eurasian/Northern Starling, Purple-winged Starling

Taxonomy. *Sturnus vulgaris* Linnaeus, 1758, Sweden.
Forms a superspecies with *S. unicolor*; formerly considered conspecific, and genetic differentiation only slight, some hybridization occurring in area of breeding overlap in SW Europe. On basis

On following pages: 41. Spotless Starling (*Sturnus unicolor*); 42. Red-billed Starling (*Poliopsar sericeus*); 43. White-cheeked Starling (*Poliopsar cineraceus*); 44. Wattled Starling (*Creatophora cinerea*); 45. Rose-coloured Starling (*Pastor roseus*); 46. Black-collared Starling (*Gracupica nigricollis*); 47. Asian Pied Starling (*Gracupica contra*); 48. Bali Myna (*Leucopsar rothschildi*); 49. Purple-backed Starling (*Agropsar sturninus*); 50. Red-cheeked Starling (*Agropsar philippensis*).

of recent molecular data, coupled with behaviour, may be only distantly related to some of the other species often assigned to present genus. Thirteen subspecies recognized.

Subspecies and Distribution.

S. v. vulgaris Linnaeus, 1758 – breeds from Iceland E to Ural Mts, S to N & NE Spain, S Italy, SE Europe and N Ukraine, also on Canary Is; non-breeding also S throughout Iberia and to N Africa.

S. v. faroensis Feilden, 1872 – Faroe Is.

S. v. zetlandicus E. J. O. Hartert, 1918 – Shetland Is.

S. v. granti E. J. O. Hartert, 1903 – Azores.

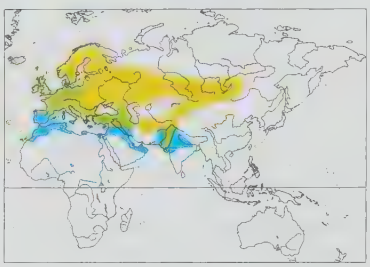
S. v. poltaratskyi Finsch, 1878 – breeds E Ural Mts E to L Baikal, S to N & E Kazakhstan, N Kirghiz Steppes and through N Dzungaria to W Mongolia.

S. v. tauricus Buturlin, 1904 – S & E Ukraine and Crimea E to S Russia (Stavropol), and Asia Minor (except E); non-breeding also Middle East.

S. v. caucasicus T. Lorenz, 1887 – Volga Delta, N Caucasus and E Transcaucasia, Azerbaijan, S Caspian Sea region and W & S Iraq.

S. v. purpurascens Gould, 1868 – W Transcaucasia, E Turkey, Georgia and Armenia; non-breeding also Egypt.

S. v. oppenheimi Neumann, 1915 – SE Turkey and N Iraq.



S. v. porphyronotus Sharpe, 1888 – breeds E Kazakhstan and extreme NW China (W Xinjiang) S to E Uzbekistan and Tajikistan; non-breeding N Indian Subcontinent.

S. v. nobilior Hume, 1879 – breeds NE Iran, S Turkmenistan and N Afghanistan; non-breeding NW Indian Subcontinent.

S. v. humii W. E. Brooks, 1876 – breeds W Himalayas (from Kashmir E to Garhwal).

S. v. minor Hume, 1873 – Pakistan (Indus valley).

Introduced (nominate race) in North America, NW Mexico, Caribbean (Jamaica and Puerto Rico), South Africa, Australia, New Zealand; now breeding also in Argentina (Buenos Aires province).

Descriptive notes. 21 cm; 55–100 g. Medium-sized, short-tailed starling with crown and nape feathers lanceolate, throat feathers also lanceolate; plumage mostly blackish, variably glossed. Male nominate race in fresh plumage has prominent pale buff to whitish tips on all body feathers, tending to mask gloss of plumage; head black with purplish-green iridescence; wing and tail brown with very narrow buff margins, some gloss on outer webs; chin and throat blackish with some purple gloss (feathers increasingly lanceolate posteriorly); breast and upper belly dark brown, glossed green, more purple gloss on flanks; lower belly and undertail coverts lack gloss, have broader and whiter tips; iris dark brown; bill black with brown or grey tinge; legs reddish-brown to chestnut-brown. Male in breeding season has lost most pale tips (especially on breast), has strong purple gloss on head and throat, green gloss on mantle, rump and breast, feathers of throat and upper breast elongated (erected in display); bill yellow, basal third steel-blue, legs deep pink. Female is similar to male, with more extensive pale tips of body feathers (tips still evident even after abrasion) and plumage generally less glossy, lanceolate feathers of head and neck shorter and less glossy; iris dark brown, pale ring on either inner or outer margin variable in colour (cream, grey, pale brown, pale yellow); during breeding, bill yellow with paler, pinkish base. Juvenile is medium brown above, wing and tail feathers edged buff, chin whitish, breast buffy white with brown tips, belly feathers pale with dark shafts and tips (producing streaked or blotched appearance), bill brownish-black, yellow gape flanges initially (disappearing with age), legs pinkish-brown; during moult, juvenile very variable in appearance as pale-tipped dark adult feathers appear, head feathers last to be replaced. Races differ mainly in colour and extent of gloss and in size: *faroensis* is larger and heavier than nominate, juvenile much darker; *zetlandicus* is intermediate between previous and nominate; *granti* is very like nominate but slightly smaller and shorter-legged, more extensively purple above; *poltaratskyi* is more purple on head and bluer below than nominate, gloss on wing-coverts greenish-purple; *tauricus* has greenish head, bluish mantle, purplish breast, bronze sheen on belly, flanks, wing-coverts and secondaries; *purpurascens* has coppery head and throat, bluish-green back and rump; *oppenheimi* is glossed green on crown, chin, throat and side of neck, purple on ear-coverts, and purple elsewhere, with green on mantle and bronze tinge on flanks; *caucasicus* has green head and upperparts, purplish-violet belly; *nobilior* similar to previous, but with head more purplish; *porphyronotus* has greenish head sharply demarcated from reddish-purple upperparts and bronzy-purple underparts, and is virtually unspotted in breeding season (but more glossy and colourful than *S. unicolor*); *humii* has head bluish; *minor* is notably smaller than other races. Voice. Male song, heard most of year (but rarely during moult), contains much variation and mimicry; male repertoire size varies with degree of social interaction, largest at large colonies, notably smaller where breeding as isolated pairs; female sings at lower intensity, generally has smaller repertoire and shorter song bouts than male, and singing apparently suppressed during breeding. (Song-learning appears to continue throughout life; males learn from males, females from other females, mimicry of other species direct from models or from other starlings.) Song of two main elements, whistles and warbling, in complex combination, starting with whistles, proceeding through song types including mimicry of other bird species, with rattles and squawks, and ending with high-pitched trills or screams; at roost-sites song probably plays a role in establishing dominance and may help to synchronize activity of individuals. Variety of calls: high-pitched scream in distress; snarl when predator approaches nest (especially when young present); short metallic "chip" on sighting predator, also during descent to a foraging or roosting site; soft "prurrp" on taking flight; harsh, high-intensity call in post-breeding flocks; repeated "chackerchacker" during aggressive encounters or aerial chases. In areas of sympatry with *S. unicolor* in NE Spain, both species share same dialect, and interspecific song-matching is frequent, with similarity of repertoire comparable to intraspecific variation of the two in areas of allopatry.

Habitat. Open country, including modified habitats, with access to suitable nesting and roosting sites; requires cavity nest-sites, typically in woodland or on man-made structures, close to open areas of short grassland for foraging. During non-breeding season exploits wide range of habitats, including moorland, saltmarshes, seashore and tidal flats, stubble fields, orchards, refuse dumps and sewage-treatment works. Roosting sites include reedbeds, scrub and trees, also bridges and buildings, even in town centres; huge winter roosts in Europe may contain more than one million birds, while in Israel reported as reaching 5–8 million; sites offer both protection from predators and favourable microclimate. Availability of invertebrate food crucial throughout annual cycle. Primarily lowlands, to 1500 m in Switzerland and 1850 m in Russia; to 2500 m in Himalayas.

Food and Feeding. Essentially omnivorous, diet including plant and animal material; much regional and seasonal variation, reflecting opportunistic response to environment. Insects taken include soil-dwelling larvae of e.g. craneflies (Tipulidae) and moths (Lepidoptera), also adults of mayflies (Ephemeroptera), dragonflies (Odonata), lacewings (Neuroptera), grasshoppers and crickets (Orthoptera), caddis flies (Trichoptera), flies (Diptera), ants, bees and wasps (Hymenoptera) and beetles (Coleoptera); other invertebrates taken are small crabs (Decapoda), spiders (Araneae), harvestmen (Opiliones), millipedes (Diplopoda), centipedes (Chilopoda), woodlice (Isopoda), earthworms (Oligochaeta) and snails (Gastropoda). Vertebrates such as frogs and newts (Amphibia) and lizards (Reptilia) eaten. Plant foods include berries and seeds of yew (*Taxus baccata*), oak (*Quercus*), apple (*Malus*), pear (*Pyrus*), cherry and plum (*Prunus*), rowan (*Sorbus aucuparia*), elder (*Sambucus*), nightshade (*Solanum*), bryony (*Bryonia*), sea-buckthorn (*Hippophae rhamnoides*), and cultivated plants such as olives (*Olea*), grapes (*Vitis*), sorghum (*Sorghum*) and cereals (wheat, oats, barley, maize, millet); olfactory sense important during foraging, as anthranilate has been used successfully as a repellent on cultivated grain. Nectar taken from flowers, including *Aloe* and *Erythrina* in South Africa (where present species introduced). Also takes kitchen scraps and other human discards of all kinds, and feeds on pellets put out for domestic stock and pets. Highly adapted for open-bill probing in grass; juveniles initially less successful in probing (as diet contains fewer soil invertebrates), and they may forage apart from adults. Prying technique employed also on seashore, in searching for ectoparasites in fur of mammals, and to expose buried cereal grains. Will pursue insects on ground and hawk flying insects. Pulls off fragments of fruit and other large food items. Forages in small to large groups, often in huge flocks in non-breeding season; also singly and in pairs during breeding.

Breeding. Season mainly Mar–Jul, with later start and shorter season in N & E of range; often double-brooded, but usually single brood in N & E; in Southern Hemisphere (introduced) Sept–Dec. Generally monogamous, but polygyny common and some males have as many as five mates (older males more successful in this respect). Solitary nester, but frequently nests clustered in colonies in Europe (introduced populations in Australia, New Zealand and South Africa nest singly); laying in colonies often closely synchronized. In areas of sympatry with *S. unicolor* in NE Spain, mixed colonies frequent, and breeding of both species is synchronized. During courtship, song by male often accompanied by peculiar rotation of half-open wings around shoulder joint. Nest a bulky structure of dry grass, conifer needles, twigs, string and other material, cup lined with softer material such as grass, feathers, moss, wool, hair and paper, fresh green leaves and flowers often placed in cup by male, built in hole in tree, cliff, building or other structure (even a wrecked ship 200 m offshore in South Africa), exceptionally in hole in ground, or nest placed on ground; generally existing cavity used, including hole excavated by other species such as woodpecker (Picidae), but occasionally will dig own hole in sand dune or soft rock; nestboxes readily occupied; competition with other hole-nesting species reported both from native range and where introduced, and sometimes usurps nest of other species; also, shortage of nest-sites can lead to intense intraspecific competition, and fighting can result in death of one of the combatants. Clutch normally 4–6 eggs, clutches laid later in season generally smaller; eggs plain pale blue, sometimes whitish; incubation mostly by female, male taking c. 25% of the duty during daytime, male contribution greater for larger clutches, incubation period 11–14 days (15 days reported in South Africa); chicks fed by both parents, when male polygynous one or more females often left to raise brood unaided, nestling period 21 days; young fed for at least five days after leaving nest. Intraspecific brood parasitism regular at low frequency, and female sometimes removes a host egg when adding her own to a clutch; female will eject eggs appearing in nest up to day when she lays, and male will do so until 3–4 days before. In North America (where present species introduced), nest occasionally parasitized by Brown-headed Cowbird (*Molothrus ater*). Hatching success high, more than 70%, fledging success more variable, 29% to 98% in different studies, with inter-annual variation in long-term studies, and second brood often less successful than first; grey squirrel (*Sciurus carolinensis*) an occasional nest predator, also American red squirrel (*Tamiasciurus hudsonicus*) in North America; in long-term study in S England, large annual differences in percentage of young returning to colony, suggesting inter-annual differences in survival or emigration (few chicks from second broods returned); among introduced populations, average 2·3 fledglings per breeding attempt on Dassen I (South Africa), and predation by introduced stoats (*Mustela erminea*) and black rats (*Rattus rattus*), also Little Owls (*Athene noctua*), significant in some years in New Zealand, where breeding success at five sites was in range 18–61% over 23 seasons. Longevity up to 21 years in the wild.

Movements. Migratory in N & E of range; tends to be resident in S & W, and in some urban regions. Among the earliest migrants returning in spring, reaching breeding areas in Belgium in Feb, Poland and Sweden in Feb–Mar, and even NW Russia (Arkhangel'sk, 65° N) by Apr. Migration primarily N–S in E of range, birds wintering S to N India and W to Afghanistan and Middle East; in W Europe a large component of movement directed to W, birds wintering from British Is S to Iberian Peninsula and N Africa, where present mainly Oct–Mar, and sometimes on Atlantic islands. Recoveries in Tunisia of individuals ringed in E Europe (Poland, Czech Republic, Slovakia, Hungary, former Yugoslavia); one from Italy found in Libya, and one from Russia recovered in Egypt. In non-breeding season, birds will gather from a wide region (radius of more than 50 km, exceptionally up to 120 km) to join communal roosts. Among introduced populations, N breeders in North America have established migratory patterns and some spend non-breeding season in Mexico; sedentary in Southern Hemisphere. Vagrants recorded in many regions of world.

Status and Conservation. Not globally threatened. Common to very common, and locally abundant. Considered one of the most abundant bird species in the world. Recent population declines reported from Britain and many areas of N Europe seem to correlate with intensification and specialization of agriculture and consequent changes in rural habitats; in Britain and Finland declines coincided with reduction in cattle farming, notably closure of dairy farms. Sustained reduction in numbers since 1970 has led to this species being red-listed as regionally endangered in Britain, where it was formerly a pest in many agricultural areas; decline driven by decrease in survival, especially of first-year birds. Concomitant increases in population and expansion of range in S Europe, although expansion in NE Spain apparently slowed in areas of sympatry with *S. unicolor*, the first of these detected around 1977; regional shifts in abundance also in North America (introduced), but on balance the overall population has probably remained stable in both regions. Introduced populations in America now widespread, from EC Alaska E in Canada to Newfoundland, and S throughout USA to NW Mexico Baja California) and Caribbean (established on Jamaica and Puerto Rico); in South America recently established in Argentina, where population increasing (origin of this population uncertain). Introduced populations elsewhere still extending ranges: in South Africa, where apparently introduced in 1897, widespread in W (S of R Orange), and expanding E towards KwaZulu-Natal and N into Free State province in E foothills; in Australia found throughout New South Wales, Victoria and Tasmania, extending N into SE Queensland and W through S South Australia, with occasional records in W Australia. Introduced population occurs throughout much of New Zealand, and this species also reaches Fiji, with vagrants on other islands in this region. Increase in numbers wintering in Japan, Korea and Hong Kong suggests possibility of an undiscovered breeding population in E Asia. In parts of its natural Eurasian range, this species is encouraged through provision of nestboxes, as claimed to reduce some insect pests, although only one study (of an introduced population in New Zealand) has confirmed any beneficial impact, and then only under very specific conditions. In contrast, it damages foodstuffs that are important to people and domestic stock and it can transmit some diseases of domestic stock; in addition, its urban roosts can damage trees, and droppings render surrounding areas dangerously slippery and deface buildings, and can also present a public-health and animal-health threat. Formerly a regular source of food in some European countries, and was in the past kept as a cagebird; little such exploitation exists today.

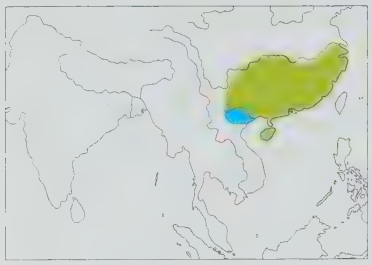
41. **Spotless Starling**

Sturnus unicolor

French: Étourneau unicolore **German**: Einfarbstar **Spanish**: Estornino Negro
Other common names: Mediterranean Starling

Taxonomy. *Sturnus unicolor* Temminck, 1820, Sardinia.
Forms a superspecies with *S. vulgaris*; formerly considered conspecific, and genetic differentiation only slight, some hybridization occurring in area of breeding overlap. On basis of recent molecular data, coupled with behaviour, may be only distantly related to some of the other species often assigned to present genus. Monotypic.
Distribution. Iberian Peninsula, S France, N Africa (Morocco, NE Algeria and Tunisia), and Mediterranean islands of Corsica, Sardinia and Sicily.

Descriptive notes. 22 cm; 70–100 g. Medium-sized starling with feathers of crown, nape, throat and upper breast greatly elongated (up to twice length of same feathers on *S. vulgaris*). Male has black body plumage with metallic iridescence, purplish on head and upper breast, oily green on back and belly; wing blackish, some mauve gloss on outer webs of innermost remiges; tail blackish-brown; iris dark brown; bill yellow with blue to bluish-black base; legs pink or reddish-pink. In fresh plumage (after post-nuptial moult), feathers have greyish margins, producing slight grey bloom; occasionally, elongated feathers of head and upper breast have small V-shaped white markings at tip, but such markings more commonly restricted to belly; male becomes more glossy as feathers abrade and all tips and margins lost; bill black in non-breeding season; legs duller and usually darker during moult period. Female is similar to male but less glossy, with shorter feathers on head and upper breast, diagnostic paler margins on wing feathers; in freshly moulted plumage, grey margins of feathers produce usually more extensive greyish bloom than in male; more often with small V-shaped white markings at feather tips, especially on vent and undertail-coverts, but tips and margins soon abrade (giving unspotted appearance); iris brown, paler inner or outer ring; bill in breeding season yellow with pinkish-brown base; legs brownish-pink. Juvenile is uniformly brown, often darker than juvenile of *S. vulgaris*, with no streaking on breast or belly, whitish chin and throat, sometimes pale margins on remiges; iris brown, bill blackish, legs brown. After post-juvenile moult, similar to non-breeding adult but with small pale feather tips all over, these still visible in spring at least on undertail-coverts, and often more developed in females; many birds, especially females, have background colour dark ash-grey rather than black. Voice. Male sings in most months; both sexes sing in winter, and at roost. Song consists of whistles and warbling phrases, which include mimicry of at least 15 other species; similar in structure to that of *S. vulgaris*, but louder (particularly the whistles). Whistles are most frequent calls in non-breeding season; harsh alarm calls, also high-pitched distress calls recorded. In areas of sympatry with *S. vulgaris* in NE Spain, both species share same dialect, and interspecific song-matching is frequent, with similarity of repertoire comparable to intraspecific variation of the two in areas of allopatry.
Habitat. Open woodland with expanses of short grass, often in association with grazing mammals; farmland, parks, gardens and cities. Up to 2500 m in mountains in summer. Communal roosts throughout the year, in summer often containing mainly juveniles, after breeding up to 20,000 birds, and may form mixed winter roosts with *S. vulgaris* of more than 100,000 birds; aerial gyrations by flocks prior to entering the roost site.
Food and Feeding. Omnivorous, animal food predominating in spring and summer, fruit and seeds in autumn and winter. Vertebrates taken include small frogs and toads (Amphibia), lizards (Reptilia), and shrews (Soricidae) and mice (Muridae); invertebrates primarily insects, mostly adult and larval beetles (Coleoptera), especially dung beetles (Scarabaeidae), weevils (Curculionidae), leaf beetles (Chrysomelidae), ground beetles (Carabidae) and grain beetles (Tenebrionidae), but including also grasshoppers (Orthoptera), ants and wasps (Hymenoptera), bugs (Hemiptera), adult flies and maggots (Diptera), caterpillars of butterflies and moths (Lepidoptera), cockroaches (Blattodea) and dragonflies (Odonata); other invertebrates taken are e.g. small snails (Gastropoda), earthworms (Lumbricidae), spiders (Araneae), mites (Acarina), ticks (Ixodida), harvestmen (Opiliones), scorpions (Scorpiones), pseudoscorpions (Pseudoscorpiones), centipedes (Chilopoda) and millipedes (Diplopoda). Plant food consumed includes seeds of docks and knotweeds (Polygonaceae), fruits of nightshade (*Solanum*), mastic (*Pistacea*), brambles (*Rubus*) and oaks (*Quercus*), and buds and flowers of elm (*Ulmus*) and poplar (*Populus*). Diet includes cultivated plants such as cherries and plums (*Prunus*), grapes (*Vitis*) and olives (*Olea*). Takes nectar from agave (*Agave*) flowers. Over the whole year in Spain, diet 60% animal food and 40% plant food. Most food collected on ground, with open-bill probing used extensively in extracting invertebrates from soil and grass; when foraging with cattle, hawks insects disturbed by the animals, removes ticks and flies from their bodies, and takes insects and seeds from dung. Feed in foliage on defoliating caterpillars during breeding season, and hawks insects; young fed predominantly with animal food. Winter flocks move in "roller-feeding" style, individuals from the rear constantly flying forward to land in front; these flocks often associated with *S. vulgaris*; in study in WC Spain, present species consistently formed larger feeding flocks than those of *S. vulgaris*.
Breeding. Season Apr to mid-Jul in Spain and Mar–Jul in Morocco; often double-brooded. Primarily monogamous; some males polygynous, and at some colonies majority of males sometimes mated with two females (experimental manipulation of male hormone levels, and provision of additional nestboxes, increased frequency of polygyny); extra-pair copulations occur, primarily by early-breeding males during incubation period of mates. Colonial nester; colonies densest where sufficient nest-sites available, e.g. in roofs. In areas of sympatry with *S. vulgaris* in NE Spain, mixed colonies frequent, and breeding of both species is synchronized. Nest built by both sexes, mainly from dry grass, lined with grass, roots, leaves and feathers, often yellow flowers included in structure, and fresh green leaves, including those of exotic eucalypts (*Eucalyptus*), may be added; male adds green leaves prior to incubation, apparently as part of courtship and to stimulate female to lay, female brings feathers during laying and incubation; sited in natural hole or old hole of woodpecker (Picidae) in tree, or in disused burrow of European Bee-eater (*Merops apiaster*) or Collared Sand Martin (*Riparia riparia*), or in old nest of White Stork (*Ciconia ciconia*), Eurasian Jackdaw (*Corvus monedula*) or sparrow (*Passer*); also artificial structures widely used, most often sites under roof tiles, or cavity in wall, building or wheat stack; nestboxes used. Clutch 4–5 eggs in Spain, usually 3–4 in N Africa, eggs plain pale blue; incubation mainly by female, period 11 days; chicks fed by both parents, both also remove faecal sacs, female doing larger share of work, nestling period 21–22 days; young fed by adults for a few days after leaving nest, within a week of fledging form flocks of juveniles, which move away from nesting area. Intraspecific brood parasitism occurs, particularly in first clutches, e.g. at two colonies over four seasons 19–27% of clutches contained parasitic eggs (parasitism up to 40% for first clutches); both male and female eject alien eggs from nest until own clutch started (success of parasitic eggs less than 10%). Of 150 eggs in Spain, 70% hatched and 51% produced fledglings; breeding success in polygynous matings suggests that female quality more important than male assistance in rearing young.
Movements. Largely sedentary. Some ringed individuals found to make extensive movements which may represent dispersal from natal area; some juveniles moved up to 700 km. Seasonal shifts of populations in S Spain imply possible short migrations; flocks from Spain seen flying towards Morocco on Oct mornings, returning at dusk. Non-breeding records from Madeira, Canary Is, Malta, Greece and Libya.
Status and Conservation. Not globally threatened. Common to locally abundant. Common and widespread in Iberia and N Morocco, and locally common in Sardinia; less numerous and more sparsely distributed in Corsica and Sicily. Range expanding in SW Europe; in areas of overlap with *S. vulgaris* expansion has slowed; first overlap area detected around 1977, in NE Spain. Causes damage to olive and cherry crops in some regions.
Bibliography. Berthold (1971), Calvo *et al.* (2000), Cambrony & Motis (1994), Celis *et al.* (2007), Cramp & Perrins (1994), de la Cruz-Cardiel *et al.* (1997), Deceuninck *et al.* (1997), Eens & Pinxten (1999), Feare (1986), Feare *et al.* (1992), Ferrer *et al.* (1991), Fry *et al.* (2000), Gallego & Balcells (1960), Hartert (1918), Lopez-Rull *et al.* (2007), McCarthy (2006), Moreno *et al.* (2002), Motis (1992, 1994, 1996), Motis *et al.* (1983), Pascual (1992), Peris (1980a, 1980b, 1981, 1983, 1984, 1988, 1991), Polo & Veiga (2006), Ruthke (1971), Smith (1965), Telleria (1981), Thévenot *et al.* (2003), Veiga & Polo (2005), Veiga, Moreno, Arenas & Sanchez (2002), Veiga, Moreno, Cordero & Minguez (2001), Veiga, Polo & Vinuela (2006), Verheyen (1994), Walter & Demartis (1972).



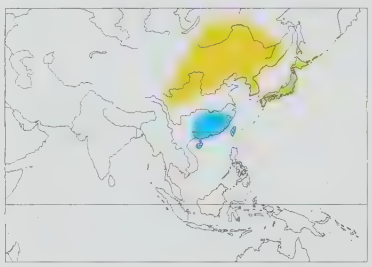
Genus *POLIOPSAR* Sharpe, 1888

42. **Red-billed Starling**

Poliopsar sericeus

French: Étourneau soyeux **German**: Seidenstar **Spanish**: Estornino Piquirrojo
Other common names: Silky Starling

Taxonomy. *Sturnus sericeus* J. F. Gmelin, 1789, China.
Genus formerly merged with *Sturnus*. Monotypic.
Distribution. SE China from S Sichuan E, S of R Yangtze, to Shanghai, S to Hainan I and Guangdong.
Descriptive notes. 22 cm; 65 g. Medium-sized starling with forehead, crown and nape feathers somewhat elongate and hackle-like. Male has white head, dark grey lower side of neck and uppermost mantle (forming diffuse but contrasting collar), slightly paler slate-grey mantle and back, rump paler; wing black, with bluish or greenish-purple gloss on outer webs of remiges, bases of primaries white, lesser wing-coverts slate-grey with white margins on outer feathers, primary coverts with white outer webs forming white wing patch; tail black, glossed green; breast and flanks grey, belly and undertail-coverts white; iris bluish, with white ring; bill red, tip sometimes black; legs chrome-yellow to dull orange. Female is similar to male but duller, with head, breast and underparts tinged brown, giving less contrast between head and body, back brown, rump pale buff,



wings and tail brown with some gloss; has grey-brown stripe on side of crown and dark malar stripe. Juvenile apparently undescribed. Voice. Song described as melodious; chattering calls from flocks, reminiscent of *Sturnus vulgaris*.
Habitat. Open areas with scattered trees in hilly country and at low altitudes; also cultivated areas, gardens and scrub.
Food and Feeding. Diet apparently insects and fruit. Forages in trees and on ground; not seen to associate with cattle. Occurs in large flocks outside breeding season.
Breeding. Nest placed in in hole in tree, in roof or in wall of house. Eggs plain blue-green. No other information available.
Movements. Presumed to be resident or partial migrant in most of range. Non-breeding visitor Nov–Mar in Vietnam and Hong Kong, which may represent migrants from N part of breeding range. Formerly a vagrant in Japan, now an annual visitor; in recent times, scarce winter visitor to Taiwan. Vagrants recorded in Korea and Philippines.
Status and Conservation. Not globally threatened. Generally fairly common. Numbers thought to be probably stable or perhaps increasing. Nowadays regular in non-breeding season in Japan, having previously been considered a vagrant there. In Hong Kong (non-breeding), communal roosts of up to 5000 individuals recorded; in C Annam (Vietnam), flock of c. 2000 birds noted in paddyfields, Feb 2008.
Bibliography. Brazil (1990), Chalmers (1986), Chen Fuguan *et al.* (1998), Cheng Tsohsin (1987), Dickinson *et al.* (1991), Étchécopar & Hüe (1983), Kennedy *et al.* (2000), Lee Kwok Shing *et al.* (2007), Ma Suquan (1989), Mees (1997), duPont (1971), Robson (2000), Zhang Chunlan *et al.* (2006), Zhang Yongpu *et al.* (2006).

43. White-cheeked Starling

Poliopsar cineraceus

French: Étourneau gris **German**: Weißwangenstar **Spanish**: Estornino Gris
Other common names: Grey/Ashy(!) Starling

Taxonomy. *Sturnus cineraceus* Temminck, 1835, Japan.
Genus formerly merged with *Sturnus*. Monotypic.
Distribution. Breeds SE Transbaikalia E to SE Russia (R Ussuri), S to C & E Mongolia, N China (E from E Qinghai and Sichuan), Korea, S Sakhalin I, Japan and S Kuril Is; non-breeding S China (including Hainan I and Hong Kong) and Taiwan.

Descriptive notes. 22 cm; 68–95 g. Medium-sized, brownish-grey starling with nape and throat feathers hackled, nape feathers also elongate. Male typically has black forehead, crown and nape with some greenish-blue gloss, cheek white with some black streaking; head plumage variable, sometimes largely dirty white with varying amounts of black (birds with mainly white head have crown and nape feathers non-glossy); mantle and back brownish-grey, rump white; wing brown with slight greenish gloss, outer webs of secondaries fringed white (forming white wingbar on closed wing); tail dark brown with slight greenish gloss, inner webs of rectrices tipped white, more broadly on outer feathers; throat to upper breast sooty-grey, sometimes with scattered white or white-tipped feathers, lower breast and flanks paler grey to off-white, belly and undertail-coverts white; iris brown, sometimes with pale yellow inner ring; bill orange to orange-yellow with dark base of lower mandible, in winter orange or yellow with dark brown tip of upper mandible and distal half of lower mandible; legs yellow-orange. Female is browner than male and lacks black cap, but has white cheek, white rump, and white tips of inner webs of rectrices. Juvenile is like female, but has brown streaking on white cheek, rump whitish, remiges and rectrices lack gloss, and has bill dark horn with darker tip, legs horn-brown. Voice. Call a monotonous "chir-chir-chay-cheet-cheet", with creaky quality; trilling begging call from nestlings.
Habitat. Open areas, including cultivated land, pastures, open woodland, parks and towns; sometimes in sparse, boggy larch (*Larix*) forest in Russia; often in riparian woodland in Mongolia. Avoids denser forest. Lowlands; up to 1200 m in Japan (Honshu), and up to at least 1300 m in N Mongolia. Communal roosts throughout the year; birds may fly up to 40 km each day to forage; some overlap in feeding areas of birds from different roosts; some roost sites and feeding areas have remained constant for more than 40 years; pre-roost assemblies up to 2 km from roost site.
Food and Feeding. Omnivorous, but diet primarily invertebrates, particularly insects. Animal food includes geckos and other lizards (Reptilia), frogs (Amphibia), earthworms (Annelida), spiders (Araneae), crayfish (Astacoidea), isopods (Isopoda), and many insects, e.g. beetles (Coleoptera), larval butterflies (Lepidoptera), grasshoppers (Orthoptera), flies and maggots (Diptera), ants and bees (Hymenoptera); mole-crickets (Gryllotalpidae) often the main food fed to nestlings. Fruits include cherries (*Prunus*), mulberries (*Morus*) and strawberries (*Fragaria*); more fruit taken in winter months, then including also *Melia azedarach*, *Sapium sebiferum*, *Cinnamomum camphora*, *Diospyrus kaki* and *Ligustrum lucidum*. Most food collected on ground. Forages on ploughed fields and on newly mown grassland, using open-bill probing to collect prey just below soil surface. In non-breeding range forages mostly in rice-growing areas. Gregarious at all times.
Breeding. Season Apr–Jul; two broods in Japan. Monogamous. Usually in colonies of up to 30 pairs; first clutches highly synchronous. Nest an untidy structure of grass, lined with feathers, built in hole in tree or under house eaves, in roof cavity or in nestbox, in Mongolia also excavates own hole in sand in steep riverbank; exceptionally, will nest in open situation. Clutch 2–10 eggs, mostly 5, clutch size larger in urban areas, also varies annually and declines during course of season; eggs pale blue-green or azure blue; incubation by both sexes, female doing most of work, period 12–13 days; chicks fed by both parents, nestling period 21–22 days. Occasional interspecific brood parasitism, female of present species laying in nests of *Agropsar sturninus*. Intraspecific brood parasitism recorded regularly, 18–24% of nests in one study; no eggs removed when parasite female adds an egg to clutch; late breeders appear to be responsible for most parasitism, behaving as floaters during early part of breeding season. Hatching success more than 80% in Japan, and 67–77% of nestlings reach fledging stage.
Movements. Summer visitor in N Japan (Hokkaido); resident in C & S Japan, where populations also augmented by winter visitors from N. Migratory in most of range. Arrives in breeding areas early, from Mar, with the majority present by early Apr; post-breeding wandering in nomadic flocks, followed by autumn departure in Oct, some birds remaining on breeding grounds until Nov. Non-breeders reach Hong Kong in Oct, and remain until Mar–Apr. Vagrants recorded in N Myanmar, NW Thailand and Philippines.
Status and Conservation. Not globally threatened. Common throughout range; very common in parts of Japan. During non-breeding season roosts can hold in excess of 50,000 individuals. Considered a pest species in Japan.
Bibliography. Genus *CREATOPHORA* Lesson, 1847

44. Wattled Starling

Creatophora cinerea

French: Étourneau caronculé **German**: Lappenstar **Spanish**: Estornino Carunculado

Taxonomy. *Rallus cinereus* Meuschen, 1787, Cape of Good Hope, South Africa.
Monotypic.
Distribution. Eritrea, Ethiopia and NW & S Somalia S to Uganda, Rwanda, Burundi, Kenya and Tanzania, also from W & S Angola and SE DRCongo S to Zambia, Malawi, Mozambique, Namibia, Botswana, Zimbabwe, Lesotho, Swaziland and throughout South Africa.

Descriptive notes. 21 cm; 64–85 g. Medium-sized, greyish starling with white rump in all plumages. Male in non-breeding condition has light grey body plumage, with white rump, and off-white belly and undertail-coverts; remiges black with bronzy sheen, some or all wing-coverts white (considerable individual variation, in part age-dependent); tail black with bronzy sheen; iris brown, small triangular patch of bare yellow skin below and behind eye; two bare dark streaks on throat extending down from base of lower mandible; bill pale brown to flesh-coloured; legs light brown. Breeding male may lose all feathers of head, chin and throat and develop pendulous wattles of variable size; skin of forehead, lores, centre of crown, chin and throat black, posterior crown, ear-covert region and area below eye bright yellow; one or more small wattles may develop on black areas on top of head, and paired pendulous wattles grow from bare throat streaks (may fuse to form single "dewlap", but great individual variation in pattern of wattle development); bill light pinkish to flesh-coloured, with black base. Female resembles non-breeding male, but remiges and rectrices dark brown with slight gloss, wing-coverts grey; some old females may have black remiges and rectrices, and even develop bald pigmented areas and wattles. Juvenile is like young female, initially has yellow bill. Voice. Song long wheezy phrases of more than 20 seconds, given during courtship approach to female, also in "undirected" way by male when perched or in group; apparently not territorial in function. Alarm call described as double squeak; trisyllabic flight call; female solicits male with high-pitched twittering.
Habitat. Lightly wooded dry savanna, also open and cultivated lands, usually with short grass; often in arid regions. Generally below 2000 m; recorded up to 3000 m in E Africa.
Food and Feeding. Diet primarily insects; also plant matter, including nectar. Insects taken include locusts (Acrididae), beetles (Coleoptera), termites (Isoptera), caterpillars (Lepidoptera), mantids (Mantodea) and lacewings (Neuroptera). Plant food includes fruit of figs (*Ficus*), berries of *Zizyphus mucronata*, *Ehretia rigida*, *Pollichia campestris* and *Azima tetracantha*, arils of *Acacia cyclops*, grapes and crushed maize (*Zea mays*); nectar taken from *Erythrina caffra*, *Schotia brachypetala*, *Acrocarpus fraxinifolius*, *Aloe marlothii*, *Grevillea* and *Agave sisalana*. At breeding colonies young fed primarily with locally abundant insects, such as locust hoppers (immature locusts), crickets (Grylloidea), karoo caterpillars (*Loxostege frustalis*), "mopane worms" (*Imbrasia belina*), and caterpillars of lucerne butterfly (*Colias electo*) or of the moth *Laphygma exemta*. Forages on ground, often employing open-bill probing (the only African starling with appropriate anatomical adaptations for this mode of feeding). Forages in association with wild and domestic ungulates; perches on white rhinoceros (*Ceratotherium simum*), blue wildebeest (*Connochaetes taurinus*) and Burchell's zebra (*Equus burchellii*) and may remove ectoparasites from them, and from sheep. Associates also with African elephants (*Loxodonta africana*), but whenever it tries to perch on them displaced by the elephants. Frequent follower of locust swarms. Scavenges at abattoirs, carrion, and rubbish heaps, probes in elephant dung, and forages in rocky intertidal zone on South African coast. Gregarious, usually in flocks of up to 30 individuals; sometimes in huge gatherings containing thousands. In S of range often associates with *Lamprotornis bicolor*, and may share roost-sites; in non-breeding season also shares roosts with *Acridotheres tristis*, *Sturnus vulgaris*, *Onychognathus morio* and Cape Weavers (*Ploceus capensis*) in South Africa, and with *Lamprotornis nitens* and *L. chalybaeus* farther N. In Kenya forages in association with *L. chalybaeus*, also with Chestnut Weaver (*Ploceus rubiginosus*) and *L. superbus*, less often with *Cinnyricinclus leucogaster* or *L. hildebrandti*.
Breeding. Often apparently opportunistic, related to abundant insect food; Jul in Eritrea, May–Aug in Ethiopia, May in Somalia, Apr–May, Jul and Dec in Kenya and Tanzania, and Nov–Apr in Botswana; in S Africa largely seasonal, Sept–Nov in winter-rainfall region, Jan–Mar in summer-rainfall zone. Monogamous; extra-pair copulations noted in captive flock. Colonial, sometimes thousands of nests covering several square kilometres, colony sometimes abandoned abruptly if food supply in area fails. Free-standing nest ball-shaped, with side entrance, made of twigs and thorny branches, lined with grass or feathers, placed 1–10 m above ground in tree or bush (both native and exotic species used); nests may be clustered together to form a single mass with separate entrances. Clutch 3–4 eggs, pale blue, sometimes with faint brown spots; incubation by both sexes, period 11 days, hatching closely synchronized within colony; chicks fed by both parents, nestling period 13–16 days; young leave nest before able to fly, and are vulnerable to avian predators at this stage.

Movements. Highly nomadic; although breeding mainly seasonal, location of colonies dependent on abundance of insect food, and movements generally not predictable. Formerly huge numbers reported in SW Uganda in association with red locust (*Nomadacnis septemfasciata*) outbreaks. In some areas, such as Zambia, a regular dry-season visitor with movements more like those of a regular migrant; also regular non-breeding visitor to Laikipia Plateau, Kenya. Recorded (non-breeding) occasionally in W Africa (Gambia, Senegal, Ghana, Nigeria, Cameroon, Gabon, PRCongo and Central African Republic); irregular visitor in Arabian Peninsula (Yemen and Oman), and vagrants recorded from Seychelles and Madagascar.
Status and Conservation. Not globally threatened. Very widespread and locally common. Population in Kruger National Park, in South Africa, estimated at more than 130,000 individuals, and in Kgalagadi Transfrontier Park, covering SW Botswana and adjacent NW South Africa, more than 16,000 birds; population can at times exceed 10,000 individuals in S Mozambique, but much less common in C Mozambique, where estimated at minimum of 1000 birds. Huge aggregations containing "tens of thousands" of individuals formerly reported in SW Uganda in association with locust outbreaks, but currently few flocks hold more than 100 birds. Breeding not reported from Uganda since 1940; also no published breeding records for Sudan, DRCongo, Angola, Zambia, Malawi and Mozambique. Breeding occurs mainly in sparsely populated regions. Formerly protected as a "locust-bird", believed to be useful in control of locusts; is now sometimes shot for causing damage in commercial grape-growing areas.

Genus *PASTOR* Temminck, 1815

45. **Rose-coloured Starling**

Pastor roseus

French: Étourneau roselin **German**: Rosenstar **Spanish**: Estornino Rosado
Other common names: Rosy Pastor, Rosy Starling

Taxonomy. *Turdus roseus* Linnaeus, 1758, Lapland and Switzerland.
Genus often subsumed into *Sturnus*. Monotypic.
Distribution. Breeds regularly from S Ukraine E to lower Volga steppes, C & E Kazakhstan, W Altai and W Mongolia, S to E Turkey, S Iran, Afghanistan and NW China (W & N Xinjiang); occasionally SE Europe W to Czech Republic, Hungary and Italy, and possibly now breeding annually in Bulgaria, also occasionally farther E in Russia (to upper R Yenisey). Non-breeding mainly India and Sri Lanka.

Descriptive notes. 21 cm; 60–88 g. Medium-sized starling with nape feathers hackled and elongate, forming long erectile crest. Male has head and neck to throat and upper breast black, glossed purple, upperparts, lower breast and belly pale pastel pink, undertail-coverts blackish; wing blackish-brown, green iridescence on secondaries; tail blackish-brown with green iridescence; iris dark brown; bill pink distally with black base during breeding, dark brown or blackish in autumn, brownish-pink in winter; legs yellowish-horn. In fresh plumage after complete moult (in late summer), male has black feathers tipped buffy grey tips, pink feathers tipped brown, black undertail-coverts dull with brown tips, remiges and wing-coverts with buff margins (abrasion of feather tips produces characteristic black-and-pink plumage). Female is similar to male but somewhat duller, with shorter crest; retains buffy feather tips in spring, so that throat, nape and undertail-coverts appear brown. Juvenile is sandy grey-brown above, rump paler and with pinkish or buff tinge (contrasting with back in flight), ear-coverts pale, wings and tail brown with buff feather margins, buff below, chin and throat paler and with dark feather centres (producing spotted appearance), pale eyering; bill horn-coloured, base bright yellowish or orange, legs pinkish-yellow or straw-coloured; first-winter bird has dull black head, crown feathers brown-tipped and not elongated, back and underparts browner than adult, undertail-coverts dull black with buff tips. Voice. Song a long series of bubbling, warbling, whistled and grating phrases, apparently not including mimicry; song given from ground in courtship, during latter stages of which female emits loud "tsili-tsili-tsili". Feeding and roosting flocks maintain constant chatter; flight call and alarm call short and harsh, resemble those of *Sturnus vulgaris*.
Habitat. Breeds on open steppes where orthopterans (locusts and other grasshoppers) abundant; colonies usually near water, often in valleys. After breeding, moves to more wooded areas. In non-breeding season found in wide variety of habitats, including wooded areas and open country. Roosts communally in thorn bushes, trees and reedbeds, often with other starling species, also with parakeets (*Psittacula*), crows (*Corvus*), *Ploceus* weavers and sparrows (*Passer*); also forms daytime roosts near feeding and drinking sites.
Food and Feeding. Insectivorous during breeding season, when diet dominated by locusts and other grasshoppers; more fruit taken after breeding, and in winter diet includes insects, fruit, seeds and nectar. Importance of locusts in diet perhaps overemphasized, although individual birds can eat 120–220 locusts (particularly flightless hopper instars of *Dociostaurus maroccanus* and *Calliptanus italicus*) per day; also takes other insects, such as bugs (Hemiptera), ants (Formicidae), beetles (Coleoptera), and moths and caterpillars (Lepidoptera), including winter moth (*Operophtera brumata*), an important pest species; spiders (Araneae), woodlice (Isopoda) and snails (Gastropoda) also eaten. Fruits taken from figs (*Ficus*), *Lonicera* and *Solanum*, also from cultivated mulberries (*Morus*), vines (*Vitis*), cherries and plums (*Prunus*), apricots (*Prunus armeniaca*), pears (*Pyrus*), raspberries (*Rubus*), dates (*Phoenix*) and chillies (*Capsicum*); fruits of *Pithecelobium dulce* important for fat-storing prior to spring migration. Seeds of cereals such as wheat, sorghum and millet taken. Nectar taken from flowers of *Bombax*, *Butea*, *Careya* and *Erythrina*; feeds intensively at *Bombax ceiba* trees in flower, displacing sunbirds (Nectariniidae) and squirrels (Sciuridae), but dominated by *Acridotheres* mynas. Most locusts taken on the ground, birds hurrying in one direction, those at the back of flock flying over those in front so that group moves in a "roller-feeding" manner. Sometimes accompanies cattle. Highly gregarious at all times; forages in flocks, sometimes large ones.
Breeding. Breeds May–Jul; short season closely tied to food availability, and breeding may be abandoned prematurely if food supply fails. Monogamous. In large colonies often of hundreds and up to several thousands of nests, occasionally tens of thousands. Nest built rapidly, by both sexes, from grasses and twigs, lined with finer grasses and feathers (often starling feathers), cup may include aromatic plants such as wormwood (*Artemisia*), giant fennel (*Ferula*) and the poaceous grass *Aeluropus*; placed in hole, most frequently in interstice between stones on scree slope, sometimes in crack in rock or cliff, among stones on railway embankment or quarry, in hole or crevice in building, under eaves or in thatch, or occasionally hole of Collared Sand Martins (*Riparia riparia*) used or even hole in tree, particularly willow (*Salix*); in dense colonies adjoining nests may coalesce. Clutch 3–6 eggs, pale blue to azure blue; incubation by both sexes, both may develop brood patch but female much more frequently, period estimated at 15 days; chicks fed by both parents, nestling period c. 24 days; young fed by both adults for a short period after leaving nest. Intraspecific brood parasitism reported; frequency not known. No information on breeding success, but numerous avian and mammalian predators attracted to colonies.
Movements. Migratory; also nomadic during post-breeding dispersal, which begins when most nestlings have fledged, usually in Jun–Aug. Non-breeding grounds in Indian Subcontinent, primarily in N peninsular India from Gujarat E to Bihar and S through the Deccan, also regularly in Sri Lanka; sometimes common in Kerala (SW India). Autumn migration from Jul to mid-Oct, adults leaving before juveniles; in W of breeding range migration almost due W–E, but farther E predominant direction SE, with passage through Pakistan into India on narrow front between Kangra Valley and Baluchistan. Among earliest winter migrants reaching India, remaining until Mar–Apr; on rutun migration reaches breeding areas from mid-Apr to early Jun. Also irregular non-breeding visitor in small numbers in Oman. Recorded as accidental visitor in Iceland, Faroes, Britain, Ireland, France, Spain, Fennoscandia, Germany, Poland, Austria, Switzerland, Malta, Albania, N Africa (Algeria E to Egypt), Lebanon, Jordan, Kuwait, Seychelles, E Asia (SW Myanmar; Thailand; Malaysia; Shanghai, in China; Korea); recently recorded also in sub-Saharan Africa in Ethiopia and in South Africa (Kgalagadi Transfrontier Park). Individual ringed in Hungary recovered 10 months later in W Pakistan, 4800 km to SE.
Status and Conservation. Not globally threatened. Common to abundant; breeding colonies can contain tens of thousands of nests, and migrating birds have been estimated in millions. Location of breeding colonies in any one year determined largely by local abundance of Orthoptera, and colonies therefore established erratically outside main area, sometimes extending W as far as Czech Republic, Hungary and Italy and in most of SE Europe; possibly now an annual breeder in Bulgaria. Widely regarded as beneficial because it consumes large quantities of grasshoppers and locusts. Conversely, may also damage mulberries, grapes and cereal crops in post-breeding period, when fruit and other plant material more important in diet.

Genus *GRACUPICA* Lesson, 1831

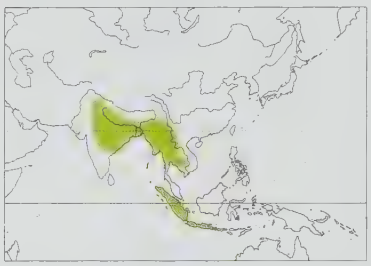
46. **Black-collared Starling**

Gracupica nigricollis

French: Étourneau à cou noir **German**: Schwarzhalsstar **Spanish**: Estornino Cuellinegro
Other common names: Black-collared Myna, Black-necked Starling

Taxonomy. *Gracula nigricollis* Paykull, 1807, Canton (Guangzhou), Guangdong, China.
Genus often merged with *Sturnus*. Monotypic.
Distribution. Myanmar (except W & SW) and S & SE China (S from Yunnan and N Fujian) S to N peninsular Thailand and S Indochina. Introduced in Taiwan.

Descriptive notes. 28 cm; 122–178 g. Large starling with mostly pied plumage; feathers of forehead and crown hackled. Has forehead, crown, chin and throat white, slightly iridescent black collar around neck and down to upper breast; mantle and back dark sepia-brown, rump white; wing darker sepia-brown, remiges blackish, secondaries tipped white, primary coverts white, secondary coverts blackish-brown with prominent white tips; tail chocolate-brown, rectrices tipped white, broader tips on outermost feathers; lower breast, belly and undertail-coverts white, often tinged with grey-brown (looking dirty); iris dark brown with narrow fleshy-grey outer ring, bare yellow skin around eye extending in triangle behind eye; bill blackish; legs lead-grey to dull purplish-brown. Sexes alike. Juvenile lacks black collar, has head, neck and breast brownish-grey, streaked white, back browner than adult. Voice. Calls include shrill rattles and melodious notes and harsh whistles; disyllabic "tiu tiu" during display between partners; harsh "kraak" probably an alarm call.
Habitat. Open areas, including grassland, rice stubble, cultivated fields, lawns and settlements; also dry, stunted forest. Mainly lowlands, but recorded to 2000 m.
Food and Feeding. Earthworms (Oligochaeta), grasshoppers and crickets (Orthoptera); seeds also recorded as eaten. Forages primarily on the ground, including among grazing cattle. Generally in pairs or small groups.



Breeding. Season Mar–Jul in China, and Feb–Aug in Myanmar and SE Asia; multi-brooded. Presumed monogamous. Often in colonies, within which timing by pairs may be synchronized. Nest a large untidy, domed structure, built from twigs, rice straw and grasses, lined with feathers, grass and flowers, placed in tree in field or near open area; nest may be reused in successive years. Clutch 3–5 eggs, blue to blue-green. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Common throughout most of range. Introduced population in Taiwan reported as numbering more than 700 individuals in 1999. Deforestation may allow this species to extend its range. Possibly occurs in NE India (in dry valleys of S Assam hills), but no confirmed records.
Bibliography. Bourlière (1953), Chen Fuguan *et al.* (1998), Deignan (1945), Étchécopar & Hüe (1983), Leven & Corlett (2004), Lin Rueyshing (2001), Rasmussen & Anderton (2005b), Robiller (1990), Robson (2000), Smythies (1986), Sontag (1998, 2002), Wang Shuzhen *et al.* (1983), Wells (2007).

47. **Asian Pied Starling**

Gracupica contra

French: Étourneau pie **German**: Elsterstar **Spanish**: Estornino Pío
Other common names: Pied Starling, (Asian/Indian) Pied Myna

Taxonomy. *Sturnus contra* Linnaeus, 1758, Calcutta, India.
Genus often merged with *Sturnus*. Five subspecies recognized.
Subspecies and Distribution.
G. c. contra (Linnaeus, 1758) – extreme E Pakistan (Lahore area), N & C India (E to W Assam, S to extreme N Karnataka and N Andhra Pradesh), S Nepal and Bangladesh.
G. c. sordida (Ripley, 1950) – NE India (E Assam).
G. c. superciliaris (Blyth, 1863) – NE India (Manipur), Myanmar (except S & E) and SW China (SW Yunnan).
G. c. floweri (Sharpe, 1897) – S & E Myanmar, S China (SE Yunnan), Thailand (except E), NW Laos and Cambodia.
G. c. jalla (Horsfield, 1821) – Sumatra, Java and Bali.
Introduced (presumed nominate race) in United Arab Emirates and Saudi Arabia; also W India (Bombay area) and Japan.

Descriptive notes. 22 cm; 76–90 g. Medium-sized starling with feathers of forehead and crown hackled, and feathers of hindcrown and nape elongated. Nominate race has forehead and cheek area white, rest of head to neck and down to upper breast black, some iridescence on hindcrown, nape and throat; some neck and nape feathers have white shafts and greyish webs, producing faint streaking; mantle and scapulars blackish with sepia-brown tinge, white line along edge of scapulars, back blackish, rump white; wing black, outer lesser coverts and inner median coverts white (forming white wingbar); tail black; lower breast, belly and undertail-coverts greyish-white; iris brownish-orange, bare skin around eye orange; bill red, light horn-coloured or yellow tip; legs yellowish-brown. Sexes alike. Juvenile is browner than adult, lacks iridescence, has cheek patch dirty white. Race *sordida* has underparts greyer than nominate, also less streaking on side of neck, none on nape; *superciliaris* has forehead and crown streaked white, lower breast and belly smoky grey; *floweri* has hackled feathers of forehead and crown buffy white, more gloss on black of mantle, throat and upper breast, legs paler; *jalla* is whiter below, has more extensive bare skin around eye. Voice. Song, by both sexes, a prolonged series of phrases with shrill churrs and a few croaking and buzzing notes, more melodic than that of *Acridotheres tristis*; mimicry of other birds sometimes included. Loud "staar-staar" warning calls, shrill "shree-shree" alarm calls, also trisyllabic flight calls, and myna-like disyllabic calls; chuckles, whistles and high-pitched warbling also described.
Habitat. Open areas with scattered trees and wet ground, often near cultivated areas and human habitation; sewage farms and refuse tips. Mainly in lowlands.
Food and Feeding. Omnivorous, diet includes animal food, fruit, nectar and flowers, and seeds. Fruits taken include those of figs (*Ficus*), *Zizyphus*, *Syzigium* and *Lantana camara*; nectar taken from *Bombax* and *Erythrina*, flower parts of *Butea* and *Grevillea* eaten; cereal grains, including wheat, consumed. Animal food includes frogs (Amphibia), worms (Annelida), snails (Gastropoda), spiders (Araneae), ticks (Ixodidae), and many insects, e.g. grasshoppers, crickets and mole-crickets (Orthoptera), earwigs (Dermaptera), cockroaches (Blattodea), termites (Isoptera), bugs (Hemiptera), flies (Diptera), beetles (Coleoptera), ants, bees and wasps (Hymenoptera), and caterpillars (Lepidoptera). Forages predominantly on the ground, in marshy grassland, on lawns and fields; follows cattle to catch insects disturbed by them, also follows plough on fields. Usually in pairs or in small parties of up to six individuals; larger groups of to 30 in non-breeding season. Communal roosts contain up to 300 individuals.
Breeding. Season Feb–Oct (mainly May–Jul) in India, May–Jul in SE Asia, and Sept–Oct in Java; occasionally double-brooded. Monogamous; ringing studies suggest that partners do not remain together in successive years. Sometimes in loose colonies; sometimes two nests 10–12 m apart in single tree, but generally large territory around nest. Nest built by both sexes, work taking 11–22 days to complete, a large domed structure 60–80 cm wide and 35–50 cm tall, entrance hole on one side (rarely, builds open nest), made from twigs, grass stems, rootlets, palm leaves and feathers, also artiifical materials such as plastic and plastic bags, wool, string, clothing fragments, cellophane and wire, inner chamber lined with finer material; placed 5–15 m above ground in tall tree, in urban areas also on telegraph or electricity pole or lamppost, and sometimes as low as 2 m. Clutch 4–6 eggs in much of range, 3 in Java; eggs pale blue; incubation mainly by female during day and entirely by her at night, period 14–15 days; chicks fed by both parents, chiefly by female, nestling period 21–25 days. Hatching success 87–92% over 4 years, fledging success 52–58% over 5 years.
Movements. Resident. Local movement in extreme NW of range.
Status and Conservation. Not globally threatened. Common to locally abundant in most of Indian Subcontinent range, uncommon in W; common to fairly common in SE Asia; common in Sumatra, Java and Bali. Common in Bombay area of W India, where introduced. Introduced populations breed also in United Arab Emirates, Saudi Arabia and Japan; rare exotic in Taiwan, where has not established itself. Range expanding in some areas; recently spread from N India W into Pakistan. Has been considered by some people to be beneficial to agriculture, as it consumes various insect species regarded as pests.

Genus *LEUCOPSAR* Stresemann, 1912

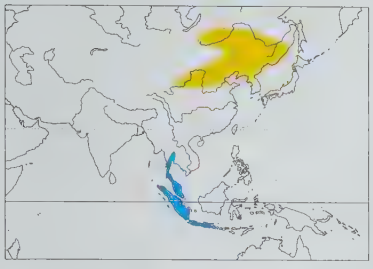
48. **Bali Myna**

Leucopsar rothschildi

French: Étourneau de Rothschild **German**: Balistar **Spanish**: Estornino de Bali
Other common names: Bali Starling, Rothschild's Myna

Taxonomy. *Leucopsar rothschildi* Stresemann, 1912, Bubunan, north coast of Bali.
Monotypic.
Distribution. NW Bali.

Descriptive notes. 25 cm; 70–115 g (captive). Fairly large, white starling with forehead feathers bristly, feathers on crown and nape hackled and greatly elongated, forming erectile crest. Plumage is white, except for black terminal band on tail, black tips on primaries; iris grey, whitish or brown, bare skin around eye and extending to point behind eye bright cobalt-blue; bill grey or brown, becoming paler horn or yellowish towards tip; legs leaden blue. Sexes similar, male having longer crest than that of female. Juvenile has much shorter crest than adult, may also have smoky tinge on back and cinnamon tinge on wings. Voice. Song a wide variety of loud chattering notes, including whistles and piercing, high-pitched notes, often accompanied by raising of crest and bowing; less fluty and repetitive than those of other mynas. Both sexes sing, often without associated display; quieter chattering sometimes accompanies bobbing display. Flight call "creer", also loud "kwuk-kwi" in flight; alarm call a loud "tschick tschick tschick".
Habitat. Open woodland with grass understorey; apparently avoids closed forest.
Food and Feeding. Omnivorous. Takes seeds of *Sterculia foetida*, small fruits of *Lantana camara*, *Deeringia amaranthoides*, *Strychnus ligustrium*, *Passiflora foetida* and *Manilkara kauki*, large fruits such as figs (*Ficus*), *Morus* and papaya (*Carica papaya*); nectar from *Erythrina*. Animal food mainly insects, such as caterpillars (Lepidoptera), ants (Formicidae), termites (Isoptera), dragonflies (Odonata) and grasshoppers (Orthoptera); occasionally worms (Oligochaeta) and small reptiles. Mostly arboreal when foraging; also collects food from ground, particularly when feeding young. Formerly noted as perching on ungulates and foraging for insects in association with the mammals. Anting observed in a bird re-introduced to the wild.
Breeding. Breeds during rainy season, Jan–Apr. Monogamous; long-term pair-bond likely, as partners allopreen and perform other mutual displays. Nest a lining of dry twigs, placed by both sexes in natural tree hole, particularly old hole of woodpecker (Picidae), 4–10 m above ground; nestboxes used in captivity. Clutch 2–3 eggs, in captivity usually 3; eggs pale blue, rarely with faint brown spots; incubation mainly by female, period 12–15 days; chicks brooded by female, fed by both parents, nestling period generally 22–24 days, in captivity up to 28 days; young fed by parents for up to 7 weeks after leaving nest, although start to feed themselves at 4–5 weeks. Hatching success in captivity 68%; productivity low, as normally only one chick survives to fledging stage. Captive females more than 11 years old no longer lay eggs.
Movements. Resident.
Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in Java and Bali Forests EBA. CITES I. Rare; has tiny population within tiny global range. Protected under Indonesian law since 1970, this species has apparently always been restricted to a limited strip across the NW third of Bali, and may have long been uncommon. First discovered in early decades of 20th century; population has since declined drastically, and range contracted greatly. From 200 individuals in early 1980s, population has not risen above 50 since. Habitat destruction, with woodland converted to coconut and kapok plantations and human settlement, has eroded original range, but capture for the local cagebird trade has been, and remains, the major threat. Current estimate of wild population is 24 birds, mostly the result of release of captive-bred individuals as part of the Bali Starling Recovery Plan; more than 1000 in captivity worldwide. In addition, releases of captive-bred birds on small island of Nusa Penida (off SE Bali) have led to establishment there of a second population; by 2008, 49 individuals had been released in Nusa Penida Bird Sanctuary and these have bred, producing total of 16 young. Until the species' security within the Bali Barat National Park can be guaranteed, however, there appears to be little prospect of re-establishing a wild population on Bali. This is considered one of only two starling species which breeds readily enough in captivity to supply the cagebird trade in Europe and North America; there are plans to legalize the breeding and trading of the species in order to open up the market and undermine illegal trade.
Bibliography. Anon. (2008b), van Balen (1996), van Balen & Gepak (1994), van Balen *et al.* (2000), Butchart & Stattersfield (2004), Collar *et al.* (2001), Dijkman (2007), Ezra (1931), Groß (2008), Harrison (1963a), van Helvoordt (1987), van Helvoordt *et al.* (1985), Hughes & Turner (1975), de Jongh (1983), de Jongh *et al.* (1982), MacKinnon & MacKinnon (1991), Pagel (1997, 1999), Plessen (1926), Roles (1973), Schürer (1977), Sieber (1978, 1983), Sontag (1991b, 1996, 2001a, 2001b, 2002), Stattersfield & Capper (2000), West & Pugh (1986), Williams & Feistner (2006).



Genus *AGROPSAR* Oates, 1889

49. **Purple-backed Starling**

Agropsar sturninus

French: Étourneau de Daourie **German**: Mongolenstar **Spanish**: Estornino Dáurico
Other common names: Daurian Starling

Taxonomy. *Gracula sturnina* Pallas, 1776, southern Dauria between Onon and Argun rivers, southeast Russia.
Genus often subsumed into *Sturnus*; alternatively into *Sturnia*. May form a superspecies with *A. philippensis*. Monotypic.
Distribution. Breeds E Mongolia, SE Russia (SE Transbaikalia E to Ussuriland), NE & C China (NE Inner Mongolia and Heilongjiang S to S Gansu and Shandong) and N Korea; non-breeding SE Asia and Greater Sundas.

Descriptive notes. 17 cm; 100 g. Small, short-tailed starling. Male has grey head to upper mantle, small patch of glossy purple feathers on rear crown, scattered glossy purple feathers on upper mantle; lower mantle and back glossy purple, rump white or pale brownish; scapulars glossy purple with broad white tips (prominent scapular band); brown primaries, glossy green secondaries and primary coverts, greater and median secondary coverts glossy purple with white tips; tail black with green gloss, outer rectrices with white on outer webs; chin to breast and flanks pale grey, belly and undertail-coverts creamy white; iris dark brown; bill black in breeding season, with pale base during non-breeding; legs greenish-grey. Female differs from male in having forehead, crown and mantle mousy brown, rump paler, chin to breast and flanks pale brown, wing brown, inner secondaries paler, secondary coverts buffy white, tail brown with slight mauve gloss. Juvenile is generally grey, back brownish, lacks nape patch. Voice. Song a varied mix of whistles, trills and chatters, including some mimicry. Calls include loud crackling sounds, also soft "prrp" flight call; grating buzz followed by short sharp yap, "grzzz-kwip", noted in Korea.
Habitat. Breeds in forest steppe, mixed forest, forest clearings, riparian woodland and villages, mainly in lowlands. On passage and in in non-breeding range occurs in woodland edge, secondary growth, coastal vegetation, cultivation, fallow lands, gardens and parks.
Food and Feeding. Diet primarily insects; also earthworms (Oligochaeta) and fruit, some seeds including arillate seeds of acacias. Insect food includes moths and caterpillars (Lepidoptera), flies (Diptera), and locusts and other grasshoppers (Orthoptera), alate termites (Isoptera); fruit such as *Fagraea fragrans*, *Sambucus latipinna*, *Ficus*. Forages on ground, by probing, also hawks insects in air; also gleans from leaves and flowers. In pairs and small groups when breeding; in non-breeding season gregarious, in small to large flocks, often with *Aplonis panayensis*; flocks of more than 150 individuals noted in Java in Nov and Jan. In winter communal roosts in reedbeds and trees, in Singapore together with *Acridotheres tristis*, *Acridotheres javanicus* and *Aplonis panayensis*, but tends to segregate with conspecifics.
Breeding. Breeds May–Jun in Russia and Korea. Monogamous. Solitary, nests normally 50–80 m apart. Nest built by both sexes, from dry grasses, sedges, leaves, roots and paper, sometimes sparsely lined with feathers, placed 3–10 m above ground in hole, usually in tree, including old hole of White-backed Woodpecker (*Dendrocopos leucotos*), or in wall of house or other building; accepts nestboxes. Clutch 3–7 eggs, normally 5–6, eggs various shades of blue; incubation of eggs and feeding of chicks done by both sexes, no information on duration of incubation and nestling periods. Nest sometimes parasitized by *Poliopsar cineraceus*.
Movements. Migratory, arriving in N breeding areas in May, leaving Russia in late Jul and Korea in Sept–Oct. Local winter visitor in C & S Thailand, Peninsular Malaysia and Singapore, and in Sumatra and Java; present in Singapore Oct–Apr. Recorded widely on passage through much of China and SE Asia. Vagrants recorded in N & S Indian Subcontinent, also Andaman Is and Nicobar Is.
Status and Conservation. Not globally threatened. Fairly common to uncommon in breeding range. Rather local in much of non-breeding range, but not uncommon in Singapore. In Korea encouraged to nest in forests through provision of nestboxes, as considered beneficial in controlling insect pests. Roost-sites in Singapore sometimes regarded as a problem, but they contain small numbers of present species compared with those of other sturnid species.

50. **Red-cheeked Starling**

Agropsar philippensis

French: Étourneau à joues marron **German**: Violettrückenstar **Spanish**: Estornino Carirrojo

Other common names: Violet-backed/Chestnut-cheeked Starling, Japanese Small Starling, Red-cheeked Myna

Taxonomy. *Motacilla Philippensis* J. R. Forster, 1781, Philippines.
Genus often subsumed into *Sturnus*; alternatively into *Sturnia*. May form a superspecies with *A. sturninus*. Monotypic.
Distribution. Breeds on S Sakhalin, Japan (S, including offshore islands of Rishiri-to, Teuri-jima and Sado, to C Honshu), S Kuril Is (S from Iturup), and Askold I (off Vladivostok, in SE Russia); non-breeding Ryukyu Is, Philippines and N Borneo.

Descriptive notes. 17 cm; c. 50 g. Small starling with short tail. Male has forehead and crown buffy white, mantle and back glossy violet; rump pale salmon with some purple feathers, sometimes all purple; wing dark brown with glossy green on remiges, outer secondaries white at base, median coverts white (prominent wingbar); tail black with green gloss, outer web of outer rectrix pale salmon; chin white with orange suffusion, throat white; cheek and side of neck brick-red, this colour sometimes extending onto upper breast; breast and flanks pale grey, belly whitish, shading to buffy salmon on lower belly and undertail-coverts; iris dark brown; bill grey or blackish; legs olive-green or bluish-horn. Female is duller than male, lacks red on cheek, has crown and back buffy grey, rump ochre, underparts buffy white; wing dark brown, gloss on outer webs of remiges, pale edges of outer secondaries, white tips of median wing-coverts (narrower bar on closed wing), tail dark brown. Juvenile apparently undescribed. Voice. Song described as babbling interspersed with louder calls; may include mimicry. Adults give excited "airr" calls; alarm "tschick", flight call a melodious "chrueruchu"; young in nest emit "tsirr" or "tsieee" chirps.
Habitat. During breeding season, found in open mixed deciduous woodland, agricultural land, and parks and villages, mainly in lowlands; on Honshu at 800–1500 m, perhaps because *Poliopsar cineraceus* common in lowlands; forest and higher mountains avoided. Open country and cities during non-breeding season.
Food and Feeding. Takes insects and fruit. Few details on diet of adults within breeding range; on migration feeds on fruit of *Ficus religiosa*, *Morus* and *Actinophloeus macarthur*, and nectar of *Spathodea campanulata*. Nestlings fed primarily with insects, particularly caterpillars and adult butterflies (Lepidoptera), dragonflies (Odonata), adult craneflies (Tipulidae), also ants, bees and ichneumon flies (Hymenoptera), beetles and their larvae (Coleoptera), flies (Diptera), grasshoppers and bush-crickets (Orthoptera), and shield-bugs (Heteroptera); cocoons of spiders (Araneae) and fruit of cherries (*Prunus*). Forages in treetops, by gleaning insects; diet indicates that some prey also collected on the ground. In pairs and small groups; in larger flocks in non-breeding season, and sometimes huge gatherings just before and during migration.
Breeding. Season May–Jul; date of first egg-laying on Honshu now 7 days earlier than it was 25 years ago. Monogamous. Nest in hole in tree or man-made structure, including building and nestbox, cavity sometimes without nesting material, or both sexes contribute material but male does most of building work (and may sing while holding green leaves in bill); male may continue to add green leaves during incubation and nestling periods. Clutch usually 5 eggs, later clutches smaller, progressive increase in mean clutch size on Honshu over past 25 years; eggs azure blue; incubation mainly by female, period 10–14 days; chicks fed by both parents, both bill to bill and by regurgitation, nestling period 15–22 days, typically 18 days; adults continue to feed fledged young for some days. In two studies, respectively 45% and 47% of eggs produced fledglings; in latter case, mortality from starvation and predation by blue-green snakes (*Elaphe climacophora*).
Movements. Migratory. Arrival in S Japan in late Mar, moving N to breeding grounds Apr–May; arrival Kuril Is and Sakhalin mid-May, older birds preceding yearlings. Leaves breeding areas Aug–Oct; in Kyushu hundreds of thousands of individuals assemble prior to flying S; passage recorded Korea, along E China coast and Taiwan. Non-breeding grounds in Ryukyu Is, but mainly Philippines (recorded Oct–Apr) and Borneo (Sept–Apr). Vagrant in Hong Kong, N Sulawesi region and N Moluccas.
Status and Conservation. Not globally threatened. Scarce on Sakhlin and Kuril Is; fairly common in Japan, but numbers appear to have declined in Tokyo area of Honshu. Relatively small numbers reported in non-breeding quarters, e.g. uncommon in Philippines, suggesting that main wintering areas have perhaps not yet been discovered.

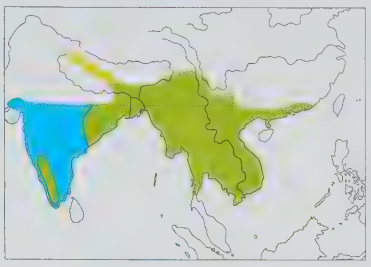
Genus *STURNIA* Lesson, 1837

51. White-shouldered Starling

Sturnia sinensis

French: Étourneau mandarin **German**: Mandarinstar **Spanish**: Estornino Chino
Other common names: Chinese/Grey-backed Starling

Taxonomy. *Oriolus sinensis* J. F. Gmelin, 1788, China.
Genus often subsumed into *Sturnus*. Monotypic.
Distribution. Breeds SE China (S of a line from E Yunnan E to Fujian, including Hong Kong and Hainan I) and NE & NC Vietnam; non-breeding Hong Kong, Taiwan, and from S Myanmar and Thailand E to Indochina, S to Malay Peninsula.



Descriptive notes. 17 cm; 61 g. Male has forehead buffy white, crown buffy white or pale grey; nape, mantle and back silver-grey, rump buffy ochre; wing dark brown to black, slight green gloss on secondaries, upperwing-coverts and scapulars white, forming large white shoulder patch; tail black with some gloss, rectrices with white or buff tips, broader on outer feathers (pale tips can be completely abraded in worn plumage); some regional variability, rectrices may be tipped with cinnamon (tail resembling that of *S. malabarica*); chin and throat buff, cheek grey-brown; breast buffy grey, belly and undertail-coverts ochreous; iris silver or white; bill blue-grey; legs grey. Female is similar to male but generally greyer, with less evident contrast, rump little paler than back, rectrices tipped dirty buff. Juvenile is like female but plumage is somewhat browner, lacks white in wing, and has scapulars grey, wing-coverts blackish, bill duller. Voice. Song apparently not described. Flight call is a soft "preep", alarm is a harsh "kaar".
Habitat. Open country, including scrub and settled areas, cultivation; lowlands, in non-breeding quarters to 400 m.
Food and Feeding. Diet includes insects, but no data from breeding range. Largely arboreal when breeding. On non-breeding grounds seen to forage on ground among cattle, and to glean leaves and twigs of trees; also takes figs (*Ficus*). Gregarious; associates with *Aplonis panayensis* and *Agropsar sturninus* on Malay Peninsula.
Breeding. Mar–Jun in Vietnam. Often in colonies, and with other species. Nest a large mass of vegetation, placed in hole in tree, rock or building, e.g. pagoda. Clutch 4 eggs, plain blue-green. No other information.
Movements. Migratory in most of range; resident in Hong Kong and N Vietnam. Post-breeding movement S to SE Asia (sometimes as far S as Singapore) and Taiwan. Accidental in Japan, Korea, Borneo and Philippines.
Status and Conservation. Not globally threatened. Rather uncommon. In China, population has recently declined markedly in numbers; locally common in Vietnam. In non-breeding quarters scarce to quite common.
Bibliography. Brazil (1990), Chen Fuguan *et al.* (1998), Cheng Tsohsin (1987), Dickinson *et al.* (1991), Étchécopar & Hüe (1983), Harrison & Smythies (1963), Kennedy *et al.* (2000), King *et al.* (1975), Leven & Corlett (2004), duPont (1971), Rasmussen & Anderton (2005b), Robson (2000), Wells (2007).

52. Chestnut-tailed Starling

Sturnia malabarica

French: Étourneau à tête grise **German**: Graukopfstar **Spanish**: Estornino Malabar
Other common names: Grey-headed/Ashy-headed Starling/Myna; Blyth's/Malabar White-headed Starling/Myna (*blythii*)

Taxonomy. *Turdus malabaricus* J. F. Gmelin, 1789, Malabar coast, India.
Genus often subsumed into *Sturnus*. Distinctive race *blythii* has sometimes been treated as a separate species on basis of plumage, proportions, sexual dimorphism, and vocal differences; claims of intergradation have been disputed. Proposed race *assamica* (described from Naga Hills, in NE India) synonymized with *nemoricola*. Type locality of species falls outside breeding range of nominate race and instead within range of race *blythii*, but in non-breeding season both forms can co-occur in this region; name presumably based on a visiting specimen. Three subspecies currently recognized.
Subspecies and Distribution.
S. m. malabarica (J. F. Gmelin, 1789) – N India (foothills in Himachal Pradesh) E to NE Arunachal Pradesh (Mishmi Hills) and N Assam, S to Orissa; occurs in remainder of peninsula, but status uncertain.
S. m. blythii (Jerdon, 1845) – SW India (from S Maharashtra S to Kerala).
S. m. nemoricola Jerdon, 1862 – NE India (S Assam) E to Myanmar, S China, Thailand and Indochina.
Descriptive notes. 20 cm; 32–44 g. Rather small starling with elongate and hackled feathers on crown, nape and side of face, and throat. Nominate race has forehead and chin white, crown, nape and side of head silver-grey with pale feather shafts (producing streaked appearance); upperparts grey, rump orange-brown; upperwing-coverts grey, tinged brownish, primaries brown, darker and with green gloss on outer webs, primary coverts black with green gloss, secondaries brown, grey margins on outer webs (broader on inner secondaries); tail grey, rectrices tipped chestnut, more broadly on outer feathers, outermost rectrices wholly chestnut; throat cinnamon with white feather shafts (producing streaking); breast, belly and vent rich cinnamon-brown, undertail-coverts variable, often partly or sometimes wholly white; iris greyish-white; bill yellow at tip, green in middle, blue at base; legs brownish-yellow or olive-brown. Sexes alike. Juvenile is grey-brown

above, paler on head, with faint pale supercilium, rusty tinge on uppertail-coverts, dirty buffish-white on side of head and underparts, dark brown wings and tail with paler edges on remiges and wing-coverts, narrow rufous tips on rectrices, iris bluish. Race *nemoricola* is paler than nominate, has head and breast greyer with white streaking, underparts dirty white with rufous less extensive, primary coverts grey or white (forming white patch); *blythii* is distinctive, larger and longer-billed than others, sexually dimorphic, male has brilliant white head and breast, grey rump washed cinnamon, flanks, lower belly and undertail-coverts rufous, primary coverts black, bases of primaries white, female differs from male in having white restricted to forehead, chin and throat, with crown and nape grey with pale streaking, breast greyish, merging into creamy rufous on lower belly and flanks, with undertail-coverts greyer, less rufous, than on male. Voice. Song a series of short hard notes and low squeaky churrs, also rapid subdued outbursts of same notes mixed with some harsher ones and thin wheezy chortles; race *blythii* song more nasal and less harsh. Calls include short buzzes and whistles, flight call disyllabic and metallic; chattering in feeding flocks.
Habitat. Open woodland and areas with scattered trees; often in young forestry plantations, also close to human habitation. Lowlands and foothills, to 2000 m in Indian Subcontinent; to 1500 m in SE Asia.
Food and Feeding. Diet includes insects, fruit, seeds and nectar; possibly also pollen and flower buds. Insects taken include caterpillars (Lepidoptera), beetles (Coleoptera), termites (Isoptera), bees (Hymenoptera), flies (Diptera), bugs (Hemiptera) and earwigs (Dermaptera); seeds of *Albizzia* and *Acacia culiformis*, fruit of *Lantana*, *Zizyphus*, *Pithecelobium dulce* and figs (*Ficus*), nectar from *Butea*, *Bombax*, *Erythrina*, *Grevillea* and *Loranthus*. Nestlings fed mainly with insects, particularly caterpillars and beetles. Highly arboreal, foraging with great agility in fine branches in flowering trees, gleaning insects; forages also in low bushes and occasionally on ground. Pairs or small groups; in larger flocks when feeding on termite alates. Roosts communally in bushes, sometimes with other species such as *Gracupica contra*.
Breeding. Season Apr–Jul in N India and Feb–May in S; Apr–Jun in SE Asia. Monogamous. Nest of grass, rootlets and twigs, placed by both parents in tree hole, often old hole of woodpecker (Picidae) or barbet (Capitonidae), 3–15 m above ground. Clutch 3–5 eggs, plain blue-green; both male and female participate in incubation of eggs and feeding of chicks; no information on duration of incubation and nestling periods.
Movements. Uncertain. Thought to be resident in most areas, but erratic movements reported which may represent local migration. In Indian Subcontinent, a summer visitor to Kathmandu valley, in Nepal, and possibly mainly a non-breeding visitor over much of peninsula; race *blythii* resident in SW India, where often joined by nominate birds during non-breeding period, even occurring in mixed flocks; vagrant in SE Pakistan and Sri Lanka. In Thailand, resident population augmented by numerous immigrants during winter.
Status and Conservation. Not globally threatened. Fairly common through greater part of range in India and SE Asia; *blythii* locally common in SW India. Some evidence of possible range extension into Pakistan in NW.
Bibliography. Amadon (1956), Ali (1932), Ali & Ripley (1972), Chen Fuguan *et al.* (1998), Deignan (1945), Devasahayam & Rema (1991), Feijen & Feijen (2008), Fleming & Traylor (1968), Jaman & Sahreen (2004), Lekagul & Round (1991), Majumdar (1984a), Mason & LeFroy (1912), McCarthy (2006), Narang & Lamba (1982), Rasmussen & Anderton (2005b), Roberts (1992), Robson (2000), Smythies (1986), Wells (2007).

53. White-headed Starling

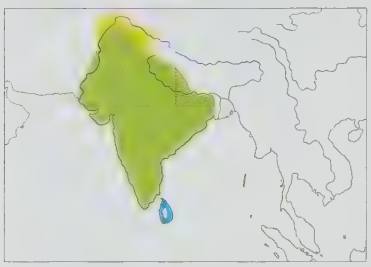
Sturnia erythropygia

French: Étourneau à tête blanche **German**: Andamanenstar **Spanish**: Estornino Cabeciblanco
Other common names: White-headed Myna, Andaman White-headed Starling

Taxonomy. *Sturnia erythropygia* Blyth, 1846, Nicobar Islands.
Genus often subsumed into *Sturnus*. Three subspecies recognized.
Subspecies and Distribution.
S. e. andamanensis (Tytler, 1867) – Andaman Is.
S. e. erythropygia Blyth, 1846 – Car Nicobar, in N Nicobar Is.
S. e. katchalensis Richmond, 1902 – Katchall I, in C Nicobar Is.

Descriptive notes. 20 cm. Small starling with much white in plumage. Nominate race has head to upper mantle and down to breast dirty white; lower mantle and back grey with purple tinge, rump and uppertail-coverts chestnut; wing black, green gloss on outer webs; tail black with green gloss, feathers with chestnut tips (broader on outer rectrices), outermost feathers almost wholly chestnut; lowermost breast and belly white, undertail-coverts chestnut; iris white, grey or bluish; bill yellow, small blue area at base; legs yellow. Sexes alike. Juvenile has head streaked brown, tawny fringes on wing-coverts. Race *andamensis* is greyer than nominate, with less gloss on wings, has rump grey, uppertail-coverts and vent buffy white, tail lacks chestnut, outer rectrices white; *katchalensis* resembles nominate, but has paler rump and uppertail-coverts (but rufous undertail-coverts). Voice. Song a loud series of disconnected notes of a very great variety of types, including musical notes, mimicry of calls of various other bird species, interminged with snarling and snorting notes, squawks and rattles.
Habitat. Forest clearings, forest edge, secondary woodland and open areas, including grassland and cultivated areas.

On following pages: 54. Brahminy Starling (*Sturnia pagodarum*); 55. White-faced Starling (*Sturnornis albofrontatus*); 56. Great Myna (*Acridotheres grandis*); 57. Crested Myna (*Acridotheres cristatellus*); 58. White-vented Myna (*Acridotheres javanicus*); 59. Pale-bellied Myna (*Acridotheres cinereus*); 60. Jungle Myna (*Acridotheres fuscus*); 61. Collared Myna (*Acridotheres albocinctus*); 62. Bank Myna (*Acridotheres ginginianus*); 63. Common Myna (*Acridotheres tristis*); 64. Vinous-breasted Myna (*Acridotheres burmannicus*); 65. Black-winged Myna (*Acridotheres melanopterus*).



Food and Feeding. Diet includes fruit, nectar and insects. Forages in trees and shrubs; extracts Lepidoptera larvae from rolled bamboo leaves. Gregarious, forms flocks of varying sizes; joins mixed-species flocks of foraging insectivores which include drongos (Dicruridae) and cuckoo-shrikes and minivets (Campephagidae). Flocks roost communally in trees.
Breeding. Season Mar–May. Nest of twigs, lined with green leaves, placed in tree hole 2–10 m above ground. Clutch 4 eggs, uniform blue. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Very common in Andaman Is; less common, but not uncommon, in Nicobars. Apparently not a forest specialist, but is restricted to islands, and could therefore become vulnerable.
Bibliography. Abdulali (1967), Ali & Ripley (1972), Davidar *et al.* (1997), Feare & Craig (1998), Grimmett *et al.* (1998), McCarthy (2006), Rasmussen & Anderton (2005b), Richmond (1902), Tikader (1984).

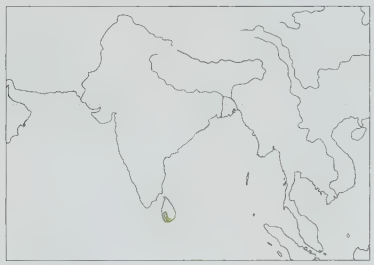
54. **Brahminy Starling**

Sturnia pagodarum

French: Étourneau des pagodes **German**: Pagodenstar **Spanish**: Estornino de las Pagodas
Other common names: Black-headed/Brahminy/Pagoda Myna

Taxonomy. *Turdus pagodarum* J. F. Gmelin, 1789, Malabar and Coromandel, southern India.
Genus often subsumed into *Sturnus*. Has occasionally been separated in a monospecific genus *Temenuchus*. Monotypic.
Distribution. NE Afghanistan E in foothills to W Nepal and West Bengal, S to E Pakistan and throughout peninsular India; non-breeding Sri Lanka.

Descriptive notes. 20 cm; 40–54 g. Distinctive small starling with long wispy crest formed by elongate and hackled crown feathers; feathers of nape and those of upper breast also hackled. Male has forehead and crown glossy black, nape cinnamon with pale shaft streaks (nape often concealed by long crown feathers); mantle, back and rump grey, tinged brown; upperwing-coverts grey, tinged with brown, primaries dull brownish-black with some white at base; tail grey-brown, all except central feather pair with white tip, white area becoming broader on outer feathers, particularly outer web of outermost feather; side of neck, chin, throat and underparts cinnamon, feathers of upper breast with pale shafts (streaked effect), flanks greyer; iris pale greenish, small bare patch of whitish skin behind eye; bill yellow distally, bluish basally, often with some dull greenish in between; legs lemon-yellow. Female is very like male, but crest shorter, hackles shorter, mantle darker. Juvenile is duller and browner on back, has crown brown without crest or hackles, underparts buffier, iris grey, bill lacks blue at base, legs flesh-coloured. Voice. Song includes huge variety of different notes and mimicry of other species, also repeated short phrases, each verse often introduced with a nasal slurr, given from perch and from ground (in different contexts); loud territorial song in short phrases, a softer advertising song, and extended song with complicated structure given by both members of pair during courtship. Calls include a series of rapidly repeated harsh shrieks, sometimes preceded by nasal note; alarm call a grating "churr", repeated in short series.
Habitat. Open deciduous forest, scrub, and cultivated areas near human habitation; especially fond of waterlogged areas. Lowlands and hills, to 1800 m.
Food and Feeding. Diet insects and other invertebrates, fruit and berries, flowers and nectar. Adults take spiders (Araneae) and snails (Gastropoda), as well as insects such as grasshoppers, crickets and mole-crickets (Orthoptera), earwigs (Dermaptera), cockroaches (Blattodea), termites (Isoptera), bugs (Hemiptera), butterflies and moths and their caterpillars (Lepidoptera), flies (Diptera), ants and bees (Hymenoptera) and beetles (Coleoptera). Fruit and berries of various shrubs and trees, including figs (*Ficus*), *Lantana camara*, *Salvadora persica*, *Salvadora oleoides*, *Zizyphus*, *Bridelia*, *Litsea*, *Mimusops hexandra*, *Thevetia neriifolia* and *Syzygium*. Nectar taken from flowers of *Erythrina*, *Bombax*, *Butea* and *Capparis* (brush-like tip of tongue suggests adaptation for nectarivory); also eat flower parts of *Madhuca indica*, *Butea* and *Grevillea*. Nestlings fed mainly with animal food, especially insects such as termites, moths, grasshoppers, also beetles, flies, bugs, ants, bees and wasps, earwigs, cockroaches; also spiders (Araneae), millipedes (Diplopoda) and earthworms (Annelida); some plant matter, including seeds and pulp of *Azadirachta indica*, *Lantana camara*, *Luffa cylindica*, *Ficus* and leaves of *Peltoforum pterocarpum*, fed to young. Forages extensively on ground, especially among cattle in moist grassland, walking rather than hopping; feeds also in small groups in flowering and fruiting trees, and hunts insects in canopy. Often forages in association with other starlings such as *S. malabarica* in trees, and with *Gracupica contra*, *Acridotheres fuscus* and *Acridotheres tristis* on the ground. Roosts communally in trees and shrubs or in reedbeds.
Breeding. Season Feb/Mar–Aug/Sept, mainly Apr–Aug, generally earlier in S of range than in N; breeding condition of males strongly influenced by photoperiod; second broods common, and sometimes three broods reared in a season. Monogamous. Solitary; also colonial where sufficient nest-holes available. Nest built by both sexes, an untidy structure of dry grass, dead leaves, paper and other material, lined with finer material, placed in hole in tree, often one made by woodpecker (Picidae) or barbet (Capitonidae), or nest of tit (Paridae) nest taken over, or sometimes hole in wall or roof of building used, or nestbox accepted. Clutch 3–5 eggs, generally 4, eggs pale blue; incubation by both sexes, female playing greater role, male reported as feeding female on nest, incubation period 12 days; chicks fed by both parents, nestling period 18–21 days. Hatching success 91–95% over four years, overall nesting success 67%.
Movements. Presumed resident over most of range. In N, summer migrant, arriving in Apr–May in Afghanistan and Kashmir E to N India. Seasonal movements, as in Goa, may be associated with the monsoon. Non-breeding visitor in Sri Lanka. Reported vagrants in SW Myanmar, S Thailand, Singapore and S China (Yunnan) possibly escaped cagebirds.
Status and Conservation. Not globally threatened. Locally common, and may be expanding its range in N. A few scattered reports from NE India and Bangladesh; corroborating reports required. Claims of former breeding in Sri Lanka questioned; now a rare and mainly coastal non-breeding visitor there. Kept as cagebird in India.
Bibliography. Akhtar (1990), Ali (1932), Ali & Ripley (1972), Bhardwaj & Kumar (2004), Chen Fuguan *et al.* (1998), Cheng Tsohsin (1987), Fleming & Traylor (1968), Henry (1971), Kotagama & Fernando (1994), Kumar & Kumar (1991), Legge (1880), Lekagul & Round (1991), Majumdar (1984a, 1984b), McCarthy (2006), Naik & Naik (1969), Narang & Lamba (1984), Patel *et al.* (1992), Raju & Rao (2004), Rasmussen & Anderton (2005b), Roberts (1992), Robson (2000), Stuart Baker (1926), Tyagi & Lamba (1984), Wells (2007).



Genus *STURNORNIS* Legge, 1879

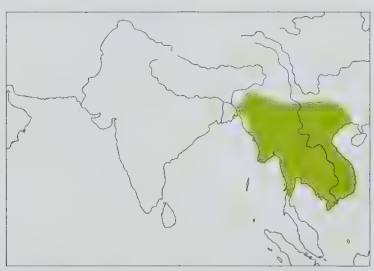
55. **White-faced Starling**

Sturnornis albofrontatus

French: Étourneau de Ceylan **German**: Greisenstar **Spanish**: Estornino Cingalés
Other common names: (Ceylon) White-headed Myna/Starling, Ceylon Starling

Taxonomy. *Heterornis albofrontata* E. L. Layard, 1854, Sri Lanka.
Genus often subsumed into *Sturnus*; alternatively, on occasion, into *Sturnia*. Species was until recently referred to as *Sturnus senex*, but that name is not applicable, as type specimen is a misidentified subadult of *Poliopsar sericeus*. Monotypic.
Distribution. SW Sri Lanka.

Descriptive notes. 20 cm. Smallish starling with pied plumage, feathers of crown, nape and upper mantle elongate and hackled. Has forehead, side of head, throat and chin white (sometimes tinged grey); crown, nape and upper mantle dull grey-black, feathers with white shafts (producing white streaking); rest of upperparts, including upperwing and tail, black with slight greenish gloss; breast, upper belly and flanks brownish-grey, tinged with lavender, feathers white-shafted (producing streaking), lower belly and undertail-coverts dirty white; iris brown with grey outer ring, or white with red-brown inner ring, or white; sometimes bluish bare skin around eye; bill greyish-green to horn, base blue-grey; legs lead-grey. Sexes alike. Juvenile is browner above than adult, has indistinct dark eyestripe, greyer below, lacks white streaking on breast. Voice. Song described as soft and sweet. Calls reported include sharp, high, downslurred "cheéwp" with strong emphasis at end, transcribed also as "cheow"; "chirp" also reported.
Habitat. Undisturbed rainforest; also visits fruiting trees in adjacent areas and in villages within forest. From c. 400 m to 1220 m, mostly below 1000 m.
Food and Feeding. Diet mainly fruit; also takes nectar and insects. Recorded items are berries of *Cinnamomum* and fruit of figs (*Ficus*), and nectar from *Bombax* and *Grevillea*. Arboreal; forages in forest canopy. In pairs and in small groups; often in large mixed-species flocks.
Breeding. Season Apr–Aug. Nest in tree hole; either no nesting material or female places a few twigs in hole. One recorded clutch, of 2 pale blue eggs. No other information.
Movements. Presumed resident; may cover long distances between feeding and roosting areas.
Status and Conservation. VULNERABLE. Rare. Has very small global range, confined to wet zone of SW Sri Lanka; estimated total population fewer than 10,000 individuals and declining; population and habitat severely fragmented as a result of degradation and clearance of humid forest. As a canopy-dwelling species, it has suffered severely from the effects of selective logging. Legally protected and present in several national parks and forest reserves, notably Sinharaja National Heritage Wilderness Area.
Bibliography. Ali & Ripley (1972), Anon. (2008b), Butchart & Stattersfield (2004), Collar *et al.* (2001), Feare & Craig (1998), Grimmett *et al.* (1998), Henry (1971), Legge (1880), Mees (1997), Rasmussen & Anderton (2005b), Stattersfield & Capper (2000), Wait (1925).



Genus *ACRIDOTHERES* Vieillot, 1816

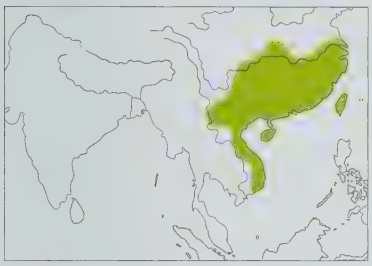
56. **Great Myna**

Acridotheres grandis

French: Grand Martin **German**: Langschopfmaina **Spanish**: Miná Grande
Other common names: Buffalo Myna, Thai Crested Myna, Orange-billed Jungle Myna

Taxonomy. *Acridotheres grandis* F. Moore, 1858, Sumatra; error = Bangkok, Thailand.
May form a superspecies with *A. javanicus* and often considered conspecific; has also been considered conspecific with *A. fuscus*. Proposed race *infuscatus* (described from lower R Chindwin, in W Myanmar) regarded as inseparable from individuals in rest of species' range. Monotypic.
Distribution. NE India (S Assam, Nagaland and Manipur) and SE Bangladesh E to Myanmar and S China (W & S Yunnan, SW Guangxi), S to N peninsular Thailand and Indochina.

Descriptive notes. 25 cm; 95–103 g. Black myna with forehead feathers elongated, forming frontal crest that may curl backwards; feathers of crown and nape elongate and hackled. Plumage is black, with some gloss on back and wings; white bases of primaries and most of exposed primary coverts, forming distinctive wing patch; white tips of rectrices, broadest on outer feathers; white undertail-coverts; iris reddish-brown; bill chrome-yellow; legs yellow. Sexes alike. Juvenile is duller and browner than adult, with very short frontal crest, buffish-white bases of chin and throat feathers producing spotted appearance, buffy undertail-coverts, wing patch smaller and white tips of rectrices narrower. Voice. Song a jumble of repeated phrases, described as a repetitive "queeter, queeter". Alarm call a harsh "kaar", flight call a soft "piu", contact call a high-pitched disyllabic "chuur-chuur".
Habitat. Open country, such as grasslands and marshes, including cultivated areas and rice paddies, also parks and gardens. Lowlands and foothills, to 1520 m.
Food and Feeding. Diet mainly insects, including alate termites (Isoptera), and other invertebrates; also seeds (rice) and berries. Forages on the ground, extracting insects from grass sward by open-



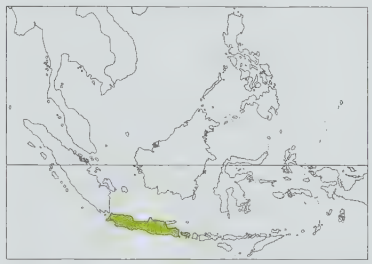
bill probing; gleans insects from leaves. Uses both cattle and buffalo (*Bubalus*) as beaters, catching insects disturbed by the mammals; also removes insects and ticks (Ixodidae) from buffalo. Forages mostly in pairs; also in flocks.
Breeding. Season Apr–Aug. Nest and untidy structure of grass and similar material, placed in hole 5 m or higher in tree, or in crown of coconut palm (*Cocos nucifera*), in house roof or in drainage hole in wall; also in disused bee-eater (Meropidae) burrows on Malay Peninsula. Clutch 4–6 deep blue eggs. No other information.
Movements. Apparently resident.
Status and Conservation. Not globally threatened. Locally common in NE India; common in SE Asia. Generally widespread in modified habitats and tolerant of people. May be expanding S in Malay Peninsula.
Bibliography. Amadon (1956), Ali & Ripley (1972), Chen Fuguan *et al.* (1998), Choudhury (1991, 2005), Deignan (1945), Feare & Craig (1998), Rasmussen & Anderton (2005a, 2005b), Robson (2000), Smythies (1986), Wells (2007).

57. Crested Myna

Acridotheres cristatellus

French: Martin huppé **German**: Haubenmaina **Spanish**: Miná Crestado
Other common names: Chinese Crested Myna, Chinese Jungle Myna, Tufted Myna, Chinese Starling

Taxonomy. *Gracula cristatella* Linnaeus, 1766, China.
Three subspecies recognized.
Subspecies and Distribution.
A. c. cristatellus (Linnaeus, 1766) – S & SE China (S from S Shaanxi).
A. c. brevipennis E. J. O. Hartert, 1910 – C & S Laos and Vietnam (except S), and Hainan I (S China).
A. c. formosanus (E. J. O. Hartert, 1912) – Taiwan.
Introduced (probably race *brevipennis*) in Peninsular Malaysia (Penang), Singapore, N Philippines (Manila region of Luzon), NW Borneo, Japan, Canada (Vancouver), Argentina (Buenos Aires province) and Portugal (Lisbon and Setubal).



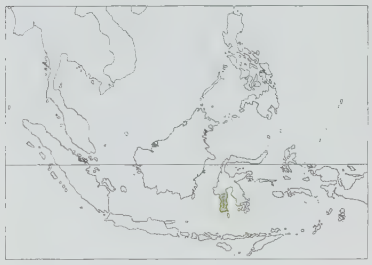
Descriptive notes. 25 cm; 108–140 g. Mostly black myna with elongated forehead feathers directed towards mid-line, forming obvious frontal crest; crown and nape feathers hackled. Nominate race has head and body black, glossy on upperparts, dull on underparts; wing brownish-black, all primaries with broad white bases (conspicuous wing patch); tail black, rectrices with narrow white tips; black undertail-coverts have white tips when plumage fresh; iris yellow to orange, sometimes yellow with orange to red outer ring; bill ivory-white with pale pink wash on base of lower mandible; legs yellow. Sexes alike. Juvenile is browner than adult, with smaller frontal crest and narrower terminal band on tail, iris bluish. Race *brevipennis* is very like nominate, but has narrower forehead feathers; *formosanus* is smaller, with green sheen on crown and back, notably longer frontal crest, sometimes broader white tips on undertail-coverts, bill greenish-yellow. Voice. Commonest vocalization a trisyllabic call with downward inflection (sometimes upward inflection), often repeated; trilling flight call and harsh "jaaay" alarm call; also croaking calls. Song a repetition of tuneless notes. Vocalizations very similar to those of *Acridotheres tristis*, but perhaps with more whistled quality. Mimics other species, in Canada (introduced) including Red-winged Blackbird (*Agelaius phoeniceus*); captives mimic human speech and other sounds in their environment.
Habitat. Open country, including rice paddies and other cultivated areas, also regularly in suburban parks and gardens; avoids woodland. Lowlands.
Food and Feeding. Diet insects and other invertebrates; also fruit, and will scavenge dead fish and human discards. Insects taken include caterpillars (Lepidoptera), cranefly larvae (Tipulidae), winged ants and ant larvae (Formicidae) and flies (Diptera). Fruits include those of *Ficus retusa*, *Lantana camara*, *Cordia cylindristachus* and *Sapium sebiferum*; in Canada (introduced population) cherry (*Prunus*), mountain ash (*Sorbus*), salmonberry (*Rubus spectabilis*), thimbleberry (*Rubus parviflorus*), black raspberry (*Rubus leucodermis*), currant (*Ribes*), crab apple (*Malus*), *Cotoneaster*, bog cranberry (*Vaccinium oxycoccos*). In S China diet 55% animal food and 45% vegetable matter; in Canada c. 60% fruits and berries, 40% insects and earthworms (Oligochaeta). Feeds extensively by probing in grass mat; also gleans insects from vegetation and hawks flying prey. Perches on backs of buffalo (*Bubalus*), from where it will collect and hawk insects. Once seen to harass a nestling Chinese Pond Heron (*Ardeola bacchus*) until latter regurgitated food. In pairs and threes; also in flocks, sometimes fairly large ones. Large nocturnal roosts formed.
Breeding. Season Apr–Aug, from Mar in Taiwan, Apr-May in Philippines; sometimes double-brooded. Monogamous, probably with long-term pair-bond. Colonial breeder where sufficient holes available. Nest an untidy mass of straw, dry grass, pine needles, feathers, wool, paper and other material, in SE Asia often sloughed snakeskins included, in Canada (introduced population) green leaves also reported, placed in natural hole in tree or in rock face, in disused nest of kingfisher (Alcedinidae), of Common Magpie (*Pica pica*) or of *Gracupica nigricollis*, or in hole in man-made structure; nestbox also accepted. Clutch 4–7 eggs, mean 4 in China, 4·8 in Canada; eggs pale blue or blue-green, rarely white; incubation by both adults, period 14 days; chicks fed by both parents, both also remove faecal pellets, nestling period 21 days. In one two-year study of introduced population in Vancouver (Canada), hatching success only 35–40%, but 79–87% of chicks fledged successfully; in later study of same population, 60% hatching success and 46% fledging success; some nest-sites were used for more than ten years.
Movements. Resident, with some dispersal.
Status and Conservation. Not globally threatened. Common to locally very common in much of native range; uncommon to common to Vietnam and Laos. Nominate race has been recorded in E Myanmar, but status there not known. Several successful introductions. Canadian population introduced in 1890s, and by 1920s estimated at 20,000 individuals, spreading S to Washington, in NW USA, but by 1950s population decreased to 2000–3000 and restricted to Vancouver area, where numbers fluctuated until, by mid-1990s, fewer than 100 individuals noted in some years; by 2003 this population considered extinct. Suggested that, being a tropical species, it followed an intermittent incubation pattern, with eggs covered for less than 50% of the time; breeding success markedly lower in cold summers. Factors in decline may have included urbanization of former agricultural land where the birds fed, reduction in nest-site availability through remodelling of older homes, increased cat predation, and decrease in urban roosting sites. This myna was first reported in Argentina in 1982, and apparently increased in numbers, with flocks of more than 100 individuals reported by 1995. In Peninsular Malaysia, population derived from introduced or escaped birds on Penang I, where still reasonably common; after initial success in Singapore, declined and has now apparently disappeared as a breeding species there. Still categorized as an invasive alien in Philippines and Malaysia, where regarded by some people as a crop pest. Feral birds in Japan restricted to Tokyo area. In Europe, escaped individuals of this species were breeding in Lisbon and Setubal regions of Portugal in 2008; a short-lived breeding group was present in Graz, in Austria, from 1983 to 1991.
Bibliography. Chen Fuguan *et al.* (1998), Chiurla & Martinez (1995), Dickinson *et al.* (1991), Hagemeijer & Blair (1997), Hails (1987), Johnson & Campbell (1995), Johnson & Cowan (1974), Kennedy *et al.* (2000), Leader (1995), Leven & Corlett (2004), Lever (2005), Mackay & Hughes (1963), McCarthy (2006), Nguyen-Clausen (1975), duPont (1971), Restall (1968b), Robson (2000), Vaughan & Jones (1913), Wells (2007), Yap & Sodhi (2004).

58. White-vented Myna

Acridotheres javanicus

French: Martin de Java **German**: Javamaina **Spanish**: Miná de Java
Other common names: Javan Myna

Taxonomy. *Acridotheres javanicus* Cabanis, 1851, Java.
May form a superspecies with *A. grandis* and often considered conspecific. Has also been considered conspecific with *A. cinereus*, and both previously included in *A. fuscus*. Monotypic.
Distribution. Java and Bali. Introduced to Taiwan, SE Thailand, Singapore, Sumatra, Lesser Sundas and Puerto Rico, and perhaps Japan.



Descriptive notes. 21 cm; 100 g. A typical blackish myna with prominent frontal crest and elongated crown feathers. Head is black, forehead, crown and ear-coverts slightly glossed; upperparts ashy black; wing brownish-black, white bases of primary feathers (least extensive on outermost primary); tail black, rectrices with white tips (broadest on outer feathers); underparts slaty-coloured, undertail-coverts white; iris pale lemon-yellow; bill and legs orange-yellow. Sexes alike. Juvenile is generally browner than adult, unglossed, with frontal tuft and crown feathers shorter, white bases of primaries and white tips of rectrices narrower, underparts paler, and pale feather margins below may produce streaked effect. Voice. Calls very like those of *A. tristis*, but with practice distinguishable to human ear.
Habitat. Cultivated areas and cities; attracted to flooded grassy areas, especially playing fields and airfields.
Food and Feeding. Omnivorous; diet includes fruit, nectar, insects and other animal matter, human refuse. Fruits of *Compnospermum auriculatum*, *Endospermum malaccense*, figs (*Ficus*) and cultivated papaya (*Carica papaya*) and banana (*Musa*) eaten; ovules from cones of *Casuarina* and nectar from *Erythrina* trees also taken. Invertebrate food includes flying ants (Formicidae), termites (Isoptera), fly maggots (Diptera), small crabs (Decapoda), earthworms (Annelida). Human refuse taken from bins or rubbish tips; will feed on carrion from roadkills and on dead animals washed ashore. Captive individuals ingested whole fruits and defecated intact seeds 2–3 hours later, suggesting important role in seed dispersal. Forages primarily on ground, occasionally in trees. In pairs and in small to medium-sized groups; occasionally in larger flocks where food abundant. Large groups assemble in tree roosts, which may be shared with *A. tristis*, also sometimes with *Aplonis panayensis* and *Agropsar sturninus*, although apparently some segregation of species within roost.
Breeding. Breeds throughout year in man-modified environments with abundant food; breeding recorded Apr–May and Sept in Java prior to 1940. Monogamous. Nest an untidy structure of grasses and similar material, placed in natural hole in tree (up to 10 m above ground), in crown of palm (nest then a mass of grass and palm fronds) or in base of bird's-nest fern (*Asplenum nidus*), or in hole in wall, building, bridge or other man-made structure, including lamppost and even a bus in service. Clutch 2–5 eggs, uniform bluish; in captivity, incubation period 13–14 days. No other information for wild-living birds.
Movements. Resident. Local movements from roost-sites to foraging areas.
Status and Conservation. Not globally threatened. Common and widespread in natural range. Elsewhere, introduced population in Singapore estimated at 168,000 individuals by 2000, and more than 20,000 in Taiwan in 1999. In Singapore in 1980s, individuals tracked by radio-telemetry used several different night roosts, and ranged over an average area of 3 km²; by 2001 there had been a significant population decline, and both total range and home area were significantly smaller. Considered an invasive alien in Singapore and Peninsular Malaysia. In Singapore initially regarded as a shy species of the suburbs, but now bold and tolerant of people; noise from night roosts is main complaint against the species, with droppings a lesser nuisance, but attempts to scare or displace the birds have had only limited success; canopy density of roosting trees and proximity to feeding areas are most important factors determining roost-sites, and thinning of canopy at existing roosts and control of refuse in vicinity can alleviate the problem.
Bibliography. Coates & Bishop (1997), Corlett & Lucas (1989), Hails (1985), Hoogerwerf & Rengers Hora Siccama (1938), Kang Nee (1992), Kang Nee & Yeo (1993), Kang Nee *et al.* (1990), Lever (2005), Lin Rueyshing (2001), van Marle & Voous (1988), Medway & Wells (1976), Peh & Chong Fong Lin (2003), Raffaele (1989), Robson (2000), Shieh Baosen *et al.* (2006), Sontag (1998), Wells (2007), White & Bruce (1986), Yap (2003), Yap & Sodhi (2004), Yap *et al.* (2002).

59. Pale-bellied Myna

Acridotheres cinereus

French: Martin cendré **German**: Fahlbauchmaina **Spanish**: Miná Cenizo

Taxonomy. *Acridotheres cinereus* Bonaparte, 1850, Sulawesi.
Has been treated as conspecific with *A. javanicus*, and both previously included in *A. fuscus*. Monotypic.
Distribution. S peninsula of Sulawesi (S from Ranteapo). Introduced to Kuching, Sarawak (Borneo).
Descriptive notes. 25 cm. A medium-sized, mostly greyish myna with lanceolate feathers of forehead erect and forming crest; crown feathers lanceolate and elongated. Has forehead blackish-

charcoal, crown black and glossy, cheek duller black; hindneck and upperparts grey, paler on rump, where some feathers have white shafts; wing dark brown, primary coverts and bases of primaries white (forming white patch); tail brownish-black, terminal third of outer rectrices white, narrower band on inner rectrices, dark feather shafts prominent; chin and throat to breast ashy grey, becoming paler to buffy grey on belly, white on vent; iris lemon-yellow to brownish-orange; bill yellow, small blue-grey patch at base of lower mandible; legs yellow. Sexes alike. Juvenile undescribed. Voice. Described as unmusical squeaky rattles and whistles.

Habitat. Open areas, including paddyfields, villages and cultivated areas; sea-level to 1500 m.

Food and Feeding. Diet presumably includes insects, also fruit. Often forages on ground among cattle, and perches on backs of these animals. In small groups; also singly and in pairs.

Breeding. Nest in hole in tree. No other information.

Movements. Presumed resident.

Status and Conservation. Not globally threatened. Locally common, but very poorly known. Introduced population in Sarawak reportedly increasing.

Bibliography. Coates & Bishop (1997), Feare & Craig (1998), Gregory-Smith (1997), Grimmett *et al.* (1998), Lever (2005), Vorderman (1898a).

60. **Jungle Myna**

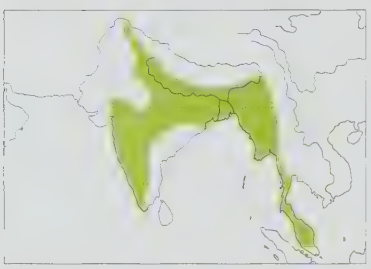
Acridotheres fuscus

French: Martin forestier **German**: Dschungelmaina **Spanish**: Miná de la Jungla

Taxonomy. *Pastor fuscus* Wagler, 1827. East Bengal, India.

Has been considered conspecific with *A. grandis*; previously treated as including *A. javanicus* and *A. cinereus* as races. Four subspecies recognized.

Subspecies and Distribution.



A. f. fuscus (Wagler, 1827) – N Pakistan E through Himalayan foothills to NE India (Assam), S in lower hills to Rajasthan and N Orissa, and to Bangladesh; also Myanmar (except N).

A. f. mahrattensis (Sykes, 1832) – W India from Rajasthan S to Kerala, E to W Tamil Nadu.

A. f. fumidus Ripley, 1950 – E Assam and Nagaland, in NE India.

A. f. torquatus W. R. Davison, 1892 – Malay Peninsula (except extreme S).

Introduced (nominate race) in Fiji; possibly established in Taiwan.

Descriptive notes. 24 cm; 72–98 g. Greyish myna with elongated and hackled forehead feathers directed upwards in mid-line to form short, bristle-like frontal crest; crown and nape feathers elongated and lanceolate. Nominate race has forehead to nape, neck and cheek glossy black; upperparts brownish-charcoal, paler on rump; wing brownish-black, bronze wash on coverts, white bases of primaries covering about half length of inner primaries; tail brownish-black, rectrices tipped white, broader white band on outer feathers; chin, throat and breast slaty grey, belly paler and tinged buff (particularly on lower belly), undertail-coverts white; iris yellow; bill orange, bluish-black base of lower mandible; legs waxy orange. Sexes alike. Juvenile is browner than adult, crown feathers less hackled and less glossy, wings and tail also browner, less distinct white tips on rectrices, browner below, throat pale, breast and belly feathers dark-centred with pale margins, producing streaked effect. Race *mahrattensis* is browner than nominate, with iris bluish-white or grey; *fumidus* is darker, sooty-coloured, with iris yellow; *torquatus* has longer and more glossy crown hackles, darker flanks and belly, off-white undertail-coverts. Voice. Song a loud, hoarse "screeow" repeated in short series; group song of harsh grating rasps rapidly repeated in staccato style, interspersed with or terminating with nasal whistles, weak wheezes, whining sounds and other notes. Common contact call a disyllabic or trisyllabic "tiuck-tiuck", repeated frequently; calls similar to those of *A. tristis*, but higher-pitched.

Habitat. Forest edge and clearings, deciduous woodland near open areas, including cultivated lands, tea plantations, villages and coastal plains; primarily in lowlands and foothills, but to 2000 m in Himalayas. In Fiji (introduced population) primarily in man-modified habitats, occasionally in secondary forest.

Food and Feeding. Diet includes insects, fruit, seeds and nectar. Insect food comprises grasshoppers, mole-crickets and crickets (Orthoptera), termites (Isoptera), beetles (Coleoptera), ants (Formicidae), caterpillars (Lepidoptera), bugs (Hemiptera) and fly larvae (Diptera). Fruits of figs (*Ficus*), *Cordia cylindristachus*, *Lantana camara*, *Capsicum* and *Litsea*; seeds of *Albizia*, *Coriandum*, cloves (*Syzygium*), groundnuts (*Arachis*), as well as cereal grains. Feeds in flowering trees and takes nectar from *Erythrina*, *Bombax*, *Butea*, *Careya* and *Spathodea*; pollen collects on crest, and species is considered an important pollinator of these plants. Also takes household food scraps, and forages at refuse dumps. Forages largely on ground, especially in grasslands grazed by cattle; frequently perches on cattle, and hawks insects disturbed by them. Uses open-bill probing to collect insects in grass. Sometimes feeds in trees and bushes, when food sources abundant there. Commonly in flocks; also in pairs. Roosts communally at night in reedbeds, sugar cane and trees, sometimes with other bird species, including *A. tristis* and *Pastor roseus*. In Fiji (introduced), roosts contain fewer than 30 individuals, and not associated with *A. tristis*.

Breeding. Season Jan–Jul; in India Apr–Jul in N and Feb–May in S; Jan-May in Malaysia; multi-brooded. Monogamous. Colonial breeder when sufficient nest-sites available. Nest a simple structure lined with twigs, roots, feathers and human artefacts, often sloughed snakeskins included, placed in hole in tree, sometimes old hole of woodpecker (Picidae), 2–6 m above ground; artificial structures such as drainage holes in walls also used; holes in limestone cliffs in Malaysia. Clutch 3–6 eggs, turquoise blue; both sexes participate in incubation of eggs and feeding of young; no information on duration of incubation and nestling periods.

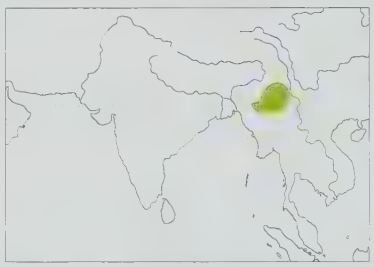
Movements. Generally resident; seasonal movements in some regions, such as Nepal. In NE India, race *fumidus* recently recorded in Calcutta (S West Bengal), far W of normal range.

Status and Conservation. Not globally threatened. Locally common in Indian Subcontinent; uncommon to locally common in Myanmar and Malay Peninsula. Was introduced in Fiji deliberately as a means of controlling grasshopper pests in sugar-cane plantations; established on Viti Levu and offshore islands, and recorded on Vanua Levu. Records in Tonga and Samoa presumed to involve vagrants from Fiji; apparent successful colonization of Samoa has raised fears that this species could compete for nest-sites with endemic Blue-crowned Lorikeet (*Vini australis*). In Taiwan, more than 1900 individuals reported in 1999. Considered a pest in parts of range; damages fruit in orchards in India, also causes damage to groundnuts and cloves.

Bibliography. Ali (1932), Ali & Ripley (1972), Beichle & Baumann (2003), Chatterjee *et al.* (2007), Fleming & Traylor (1968), Inskipp & Inskipp (1991), Lekagul & Round (1991), Lever (2005), Lin Rueyshing (2001), McCarthy (2006), Muse & Muse (1982), Narang & Lamba (1984), Raju & Rao (2004), Rasmussen & Anderton (2005b), Roberts (1992), Robson (2000), Watling (1975, 1982), Wells (2007).

61. **Collared Myna**

Acridotheres albocinctus



French: Martin à collier **German**: Halsbandmaina **Spanish**: Miná Acollarado

Other common names: White-collared Myna

Taxonomy. *Acridotheres albocinctus* Godwin-Austen and Walden, 1875, Manipur, India.

Monotypic.

Distribution. NE India (Manipur valley), N Myanmar and S China (NW Yunnan).

Descriptive notes. 25 cm. Relatively large, distinctive myna with white collar; feathers of forehead hackled and erect, forming short crest, crown and nape feathers elongated and lanceolate. Head black, slightly glossy, overall glossy grey-black above, slightly paler, duller, greyish-black below; pale collar formed by buffish-white feathers (white when tips abraded) at side of neck and throat, on nape white tips form broken band; black undertail-coverts tipped white, producing barring; wing black, small white wing patch formed by white bases of primaries; tail black, tipped white (white tips are sometimes absent on inner feathers); iris pale blue or azure-blue; bill orange-yellow; legs yellow. Sexes alike. Juvenile is browner than adult, with pale throat and pale patch on side of neck formed by buffy-white feather tips, forehead feathers bristly but no crest. Voice. Apparently undescribed.

Habitat. Open grassland, moist areas, including marshland, and cultivated lands, also villages; generally between 800 m and 1200 m, but to 1525 m in Myanmar.

Food and Feeding. Diet includes animal and plant food: grasshoppers (Acrididae) and other insects, also small vertebrates (frogs, lizards); cereal grains, nectar and fig (*Ficus*) fruits. Forages mostly on ground; also in trees. Associates with cattle and buffalo (*Bubalus*). Gregarious; often in flocks with *A. grandis*.

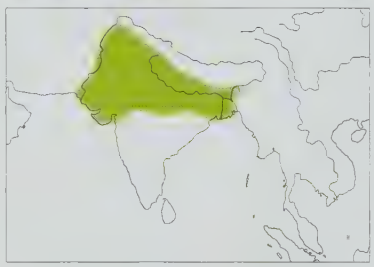
Breeding. Season Apr–Jun. Colonial. Nest a roughly built structure placed in hole in tree or bank, or in hollow in wall. Clutch 4 eggs, plain blue. No other information.

Movements. Resident. Possibly some small local movements.

Status and Conservation. Not globally threatened. Very local in NE India; uncommon to locally common in Myanmar. Very poorly known. Rare exotic in Taiwan, where presumed to involve escaped captives.

Bibliography. Ali & Ripley (1972), Chen Fuguan *et al.* (1998), Feare & Craig (1998), Grimmett *et al.* (1998), Lin Rueyshing (2001), Rasmussen & Anderton (2005a, 2005b), Robson (2000), Smythies (1986), Stresemann & Heinrich (1940a).

62. **Bank Myna**



Acridotheres ginginianus

French: Martin des berges **German**: Ufermaina **Spanish**: Miná Ribereño

Taxonomy. *Turdus ginginianus* Latham, 1790, Nadia, West Bengal, India.

Monotypic.

Distribution. N Indian Subcontinent from NC & E Pakistan and Himalayan foothills E to S Nepal and W Assam, S to Sind, NC India (Gujarat, C Madhya Pradesh, West Bengal) and Bangladesh. Introduced to Japan and United Arab Emirates; also reported from Kuwait, Oman and Saudi Arabia.

Descriptive notes. 22 cm; 64–76 g. Smallish myna with forehead feathers bristly and directed to mid-line to form short frontal crest; feathers of crown and nape elongate and lanceolate. Forehead, crown, nape and cheek are glossy black, upperparts grey; upperwing glossy black, green iridescence on secondaries, bases of primaries white, becoming chestnut-brown on inner feathers, chestnut primary coverts; tail glossy black, rectrices with chestnut tips (covering half of outer web of outermost rectrix); chin grey, breast grey with cinnamon tinge, centre of belly and undertail-coverts cinnamon, flanks grey with cinnamon wash; underwing-coverts chestnut (underwing in flight appears banded, with chestnut coverts, white primary bases, and black secondaries and outer part of primaries); iris intense brown-red, bare skin behind and below eye brick-red; bill orange-yellow; legs yellow. Sexes alike. Juvenile is dun-brown above, paler buffy below, wings and tail brown, primary coverts buffy, white bases of primaries and white tips of rectrices narrower than on adult, iris red-brown, bill and bare facial skin dull orange, legs golden-brown. Voice. Song of male includes low croaks, high-pitched whistles and warbles, also some mimicry. Raucous alarm call, and high-pitched scream during mobbing; "wheek" contact or flight call; female gave high-pitched staccato calls after copulation. Voice similar to that of *A. tristis*, but harsh and shriller in tone.

Habitat. Closely associated with man-modified habitats, both agricultural areas and cities. On farmland often found with cattle, and favours wetter areas near irrigation canals and rivers; in cities found at refuse dumps, sewage works, and wherever food likely to be discarded.

Food and Feeding. Omnivorous, diet incorporating animal food, fruit, seeds, and food waste discarded by humans. Animal food includes frog tadpoles, small snails (Gastropoda), earthworms

(Annelida), ticks (Ixodidae), spiders (Araneae), millipedes (Diplopoda), centipedes (Chilopoda), and many insects, e.g. ants and wasps (Hymenoptera), crickets, mole-crickets and grasshoppers (Orthoptera), beetles and their larvae (Coleoptera), butterflies, moths and caterpillars (Lepidoptera), termites (Isoptera), bugs (Hemiptera), cockroaches (Blattodea), earwigs (Dermaptera), mantids (Mantodea), and adult and larval flies (Diptera). Fruits taken include especially those of figs (*Ficus*), also grapes (*Vitis*) and mulberries (*Morus*); also peas (*Pisum*) and chillies (*Capsicum*), as well as *Lantana camara* and *Zizyphus* berries. Occasional visitor to flowering *Erythrina suberosa* trees, feeding on nectar. Nestlings fed with c. 95% animal food, mostly insects. Forages mostly on ground; often follows the plough and accompanies cattle. Settles on cattle and removes ticks from them. Observed to ride on airport catering vehicles. In pairs and flocks. Large communal roosts formed throughout year, in winter often in sugar cane or reedbeds, at other times in tall trees, sometimes on buildings.

Breeding. Season Mar–Aug, primarily Apr–Jun. Monogamous. Colonial. Generally excavates own tunnel in bank of river, tunnel up to 1 m long and ending in broader chamber, which it lines with straw, feathers, pieces of sloughed snakeskin, polythene and other material (in captivity, birds added fresh green leaves regularly and replaced dried leaves); sites such as brick kiln, bridge and well also utilized, and rarely nest placed in stack of sugar cane. Clutch 3–6 eggs, pale blue or greenish turquoise; incubation by both sexes, female doing more, period 13 days; both parents feed chicks and remove faecal material, nestling period 20–22 days.

Movements. Mainly resident; some seasonal or nomadic movements within range.

Status and Conservation. Not globally threatened. Common. An old record from SE Afghanistan (Kandahar), but present status there not known. Rare exotic on Taiwan, but no evidence of breeding. Causes damage locally to ripening sorghum (*Sorghum*), also to grapes and millet (*Pennisetum*); on other hand, considered an important disperser of banyan (*Ficus benghalensis*) seeds. May be beneficial to humans on balance, because it consumes large numbers of insect pests, including larvae of the noctuid moth *Ophiusa melicerte*, a pest of castor-oil plants (*Ricinus communis*), larvae of the noctuid *Helicoverpa armigera*, a pest of Egyptian clover (*Trifolium alexandrinum*), and house flies (*Musca domestica*); may also be a vector of a virus infecting *Helicoverpa*.

Bibliography. 63. Common Myna

Acridotheres tristis

French: Martin triste **German**: Hirtenmaina **Spanish**: Miná Común
Other common names: Indian/House Myna, Locust Starling

Taxonomy. *Paradisea tristis* Linnaeus, 1766, Philippines; error = India.
Races perhaps intergrade to some extent in SW India (Kerala). Two subspecies recognized.

Subspecies and Distribution.
A. t. tristis (Linnaeus, 1766) – Turkmenistan, Uzbekistan, S Kazakhstan and Tajikistan S to SE Iran, Afghanistan and almost entire Indian Subcontinent S from Himalayan foothills (except Sri Lanka), thence E to Myanmar, S China (Yunnan and Hainan), Thailand, Indochina, Malay Peninsula and Singapore.
A. t. melanosternus Legge, 1879 – Sri Lanka.
Introduced (nominate race) in SE USA (Florida), E South Africa, E & SE Australia (except Tasmania), New Zealand (North I), Hong Kong, Brunei, Sumatra, Taiwan, Japan, Saudi Arabia, United Arab Emirates, Iraq, Jordan, Israel; also in Russia, with isolated breeding reported from Moscow area and Trans-Baikal region, and in Kazakhstan (Alma-Ata); established on many oceanic islands in Atlantic (Ascension, St Helena, Tenerife), Pacific (Hawaii, Solomons, Vanuatu, New Caledonia, Fiji, American Samoa, Samoa, and many of the Cook, Society, Tuamotu and Marquesas Groups), Indian Ocean (Madagascar, Comoros, Mascarenes, Seychelles, Agalega, Chagos, Laccadives, Maldives, Andamans and Nicobars).

Descriptive notes. 25 cm; 82–143 g. Fairly large, stocky myna with brown, black and white plumage, short bristly feathers on forehead, feathers of crown and nape elongated and lanceolate. Nominate race has head glossy black, upperparts chestnut-brown; upperwing brownish-black, white primary coverts and bases of primaries; tail brownish-black, white tips of rectrices (broadest on outer feathers); chin, throat and upper breast duller and greyer than back; lower breast and flanks brown with vinous tinge, central belly buff, lower belly and undertail-coverts white; iris brown or reddish-brown, mottled with white, bare skin behind and below eye bright yellow; bill yellow, base of lower mandible greenish; legs yellow. Sexes alike in plumage, male slightly larger than female. Juvenile is duller and browner than adult, has browner head feathers lacking gloss, brownish-black chin to upper breast, pale tips of rectrices narrower and buffish. Race *melanosternus* is darker than nominate, darker brown with rufous tinge on upperparts, darker below, brownish-black feathers extending to belly, white tips of rectrices narrower than in nominate. Voice. Highly vocal at all times; mimics other birds, and captives imitate human speech. Song by both sexes throughout year, but production greatest during breeding; serves for territorial defence and pair formation. Song consists of many notes and combinations, with elements typically repeated, common sequence rendered as "hee hee chirk-a chirk-a chirk-a". Partners may duet, and neighbours can match song types. Cacophonous song also heard at night roosts, especially in morning and evening. Aggressive "chip" calls; flight call a querulous "kwerrh"; high-pitched screams in distress; scolding "chake chake" alarm call against predators, recognized by other mynas and also other species as indicating potential danger; parents may trill when approaching nest, stimulating young to beg.

Habitat. Open country, avoiding forest; dry open woodland, floodplains, grasslands, cultivated areas, villages, towns and cities; to c. 3000 m in Indian Subcontinent and to 1525 m in SE Asia. Introduced populations usually restricted to towns and cities, and areas highly transformed by human habitation, but on oceanic islands also open areas (particularly grass airstrips), secondary growth and coastal mangroves, and in Comoros occasionally enters forest; recorded to 2300 m in Hawaii, but not above 1100 m in Comoro Is.

Food and Feeding. Omnivorous, although insects often predominate in diet (stomach contents of 632 specimens from India held 82% insects by weight). Vertebrate food includes frogs, fish in drying ponds, geckos (Gekkonidae) and other small lizards, eggs and nestlings of birds, and mice (Muridae); carrion taken opportunistically. Invertebrates such as worms (Oligochaeta and Polychaeta), snails (Gastropoda), crustaceans (Decapoda and Amphipoda), ticks (Acarina), spiders (Araneae), centipedes (Chilopoda), millipedes (Diplopoda), and insects of many orders are eaten on occasion; major part of insect food made up by beetles and their larvae (Coleoptera), grasshoppers and crickets (Orthoptera), moths and butterflies and their caterpillars (Lepidoptera), flies and maggots (Diptera), bees, wasps and ants (Hymenoptera), alate termites (Isoptera), and bugs (Hemiptera). Plant food incorporates fruits and seeds of both wild and cultivated plants: *Glochidon*, *Vitex pubescens*, figs (*Ficus*), papaya (*Carica papaya*), dates (*Phoenix*), apple (*Malus*), pear (*Pyrus*), tomato (*Solanum lycopersicum*), strawberry (*Fragaria*), grapes (*Vitis*), guava (*Psidium*), mango (*Mangifera*), breadfruit (*Artocarpus altilis*), jackfruit (*Artocarpus heterophyllus*), maize (*Zea*), wheat and rice; nectar taken from *Sesbania*, *Spathodea*, *Careya*, *Erythrina*, *Butea* and *Bombax*, and in South Africa (introduced) from *Aloe* and *Erythrina* flowers. Nestlings initially fed with insects, and fruit included after c. 10 days. Forages on refuse dumps; collects discarded household scraps. Most foraging is done on ground, where open-bill probing used extensively; runs or flies in pursuit of insects, and follows domestic animals or agricultural machinery. Where introduced in South Africa, forages also with grazing mammals such as Burchell's zebra (*Equus burchellii*), eland (*Taurotragus oryx*), bushbuck (*Tragelaphus scriptus*) and impala (*Aepyceros melampus*). Gleans ectoparasites from cattle and bushbuck, and probably also from other ungulates. Sometimes ascends into trees and bushes, mainly for fruit and nectar, but also collects some insects there. Forages singly and in pairs, occasionally in small groups at abundant food. Communal roosts, usually in trees, can contain tens to thousands of individuals (in at least some cases, partners still roost together within such assemblages); pre-roost assemblies in trees, on ground (especially open areas such as playing fields and airstrips), or on buildings; noisy at roosts until well after nightfall; may roost with other species, particularly other starlings such as *A. javanicus*, *Aplonis panayensis*, *Agropsar sturninus*, *Sturnus vulgaris* and *Pastor roseus*, also with crows (*Corvus*), parakeets (*Psittacula*) and sparrows (*Passer*). Apparent anting activity seen in Malaysia where *Oecophylla* ants active.

Breeding. Season Mar–Aug in C Asia, in most months in Indian Subcontinent (mostly Apr–Jul over much of India; Jan–Mar, May–Jun and sometimes Sept–Nov in Bangladesh), and throughout year in SE Asia; multi-brooded; in introduced range, Sept-Mar in Seychelles, Sept–Jan in South Africa, Oct–Apr in Australia and New Zealand, and Mar–Jul in Hawaii. Monogamous; believed to pair for life. Solitary nester. Nest built by both sexes, taking up to two weeks to complete work, an untidy mass of twigs, grass and leaves, sometimes with animal hair, plastic, paper, cloth, string and other materials, placed up to 40 m above ground in hole or similar cavity; often in natural site such as tree hole or hole in cliff or bank, often utilizing hole made by another animal, sometimes in flowering head of palm tree or densely branched tree; man-made structures, such as house eaves, hole in wall or bridge, drainpipe, lamppost, air vent or abandoned vehicle or machinery, exploited extensively; took over nestboxes intended for Common Barn-owls (*Tyto alba*) in Malaysia. Clutch 4–5 eggs, pale blue, sky blue or greenish-blue; incubation by both sexes, female doing more, and only female incubating at night, period 13–18 days; hatching often asynchronous, and brood reduction may occur; chicks fed by both parents, nestling period 22–27 days; young fed by parents for several weeks after leaving nest. Nests parasitized by Great Spotted Cuckoo (*Clamator glandarius*) in South Africa (where introduced). Hatching success in India 90% and in Thailand 73 %, fledging success for natural populations in Asia 54–76% (from eggs laid), with first broods more successful (75%) than second broods (60%) or third broods (< 40%); in introduced population in Hawaii, hatching success typically less than 50% and fledging success only 22%. Adult recaptured after 7 years in Malaysia.

Movements. Resident throughout range; some local or altitudinal movement recorded. Adults seen to forage 3 km from roost; radio-tracked adults in Singapore flew on average 0·4 km from roost to feeding sites, and occupied home range of only 0·1 km². In introduced range, one ringed individual in South Africa moved 381 km over 12-month period.

Status and Conservation. Not globally threatened. Common to very common and locally abundant in original range; common or very common in many areas where introduced. Populations in S Russia and Turkey may be result of range expansion from C Asia or may have been introduced. Escaped captives commonly encountered in many areas; for example, has been found breeding in the wild in Dunkerque, in N France. City roosts, as in Singapore, responsible for noise pollution and fouling through droppings; thinning of canopy of trees and removing of potential food sources can displace the birds. Deliberate introductions often claimed to be justified as biological control of injurious insects, but benefits generally unclear, and this species has proved to cause damage to commercial fruit, notably grapes, and other crops, including groundnuts (*Arachis*) and cereals. In India considered an important agent in dispersal of seeds of neem tree (*Azadirachta indica*). Many introduced populations expanding, and the control and management of these have become a focus of effort by conservation agencies and other bodies. As this myna preys on nest contents of seabirds on islands, it can have a significant impact at some colonies of e.g. terns (Sternidae) and shearwaters (*Puffinus*); also considered a significant nest predator of St Helena Plover (*Charadrius sanctaehelenae*), an Endangered species of the S Atlantic, and causes disturbance at nests of Seychelles Magpie-robin (*Copsychus sechellarum*), which is Critically Endangered. On Silhouette I, in the Seychelles, a survey in 1996 revealed a significant decrease in present species' numbers since 1978–1979, probably related to a reduction in human population and in areas affected by human activity. Now actively controlled on Aride, numbers also reduced on Frégate I. Aggressive in breeding territory, destroying nests of other birds in vicinity, e.g. Red Fody (*Foudia madagascariensis*) on Madagascar, and may compete with indigenous species for nest-sites, e.g. with Critically Endangered Mauritius Parakeet (*Psittacula eques*) and Endangered Mauritius Kestrel (*Falco punctatus*) on Indian Ocean island of Mauritius, and with indigenous members of starling family on Pacific islands; may have contributed to declines or even extinctions of island endemics also through the introduction of alien parasites and diseases. Both native and introduced populations are hosts to blood parasites *Haemoproteus* and *Plasmodium*. In Hawaii, implicated in spread of invasive exotic plant *Lantana camara*; likely to disperse both *Lantana* and cinnamon in Seychelles.

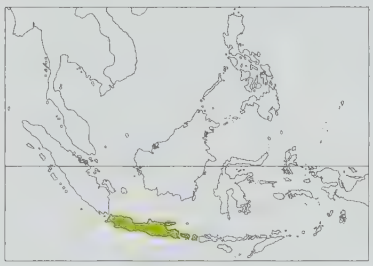
64. Vinous-breasted Myna

Acridotheres burmannicus

French: Martin vineux **German**: Burmamaina **Spanish**: Miná Birmano
Other common names: Vinous-breasted Starling, Jerdon's Starling

Taxonomy. *Sturnia burmannica* Jerdon, 1862, Thayetmyo, south-west Myanmar.
Often placed in genus *Sturnus*, but appears behaviourally and vocally closer to present genus. May form a superspecies with *A. melanopterus*. Two subspecies recognized.
Subspecies and Distribution.
A. b. burmannicus (Jerdon, 1862) – Myanmar and S China (extreme SW Yunnan).
A. b. leucocephalus Giglioli & Salvadori, 1870 – Thailand (except NW & S), Cambodia, C & S Laos and Vietnam (except N).



Descriptive notes. 22 cm. Small myna with comparatively pale plumage, forehead and crown feathers hackled and elongate. Nominate race has forehead and crown dull white, upperparts greyish-brown; upperwing brown, primaries with white bases, secondaries paler brown with dark margins, primary coverts white; tail brown, white tips of rectrices (broader on outer feathers); chin, throat and upper breast white, rest of underparts vinous, paler in centre and on undertail-coverts, greyer on flanks; underwing-coverts white; iris whitish; bill orange-red, blackish base of lower mandible; legs orange-yellow. Sexes alike. Juvenile is duller than adult, with brown crown, brown iris. Race *leucocephalus* is darker than nominate, typically has top of head greyer, back darker (producing pale collar around neck), wings and tail darker, tips of rectrices buffy, rump light buffish to whitish, breast and belly pinker, iris variable, recorded as yellow, brown, grey or black, bill yellow with red base. Voice. Loud and harsh "chew-ii", "tchew-iri-tchew-iri-tchieuw" and similar, also chattering calls during foraging; calls said to be very like those of *A. tristis* and those of *Gracupica nigricollis*.
Habitat. Open grassland, gardens and playing fields, cultivated areas and scrub, semi-desert, also large clearings in forest; very common in disturbed habitats and cultivated areas in SE Thailand. To 1500 m.
Food and Feeding. Diet presumably includes fruit and insects. Forages mainly on ground, but also in trees. In pairs and small flocks. Large, noisy communal roosts in bamboo, reeds or sugar cane.
Breeding. Season Apr–Nov; multi-brooded. Nest a large untidy mass of vegetation, placed in hole in tree, under house eaves or in thatched roof. No further information.
Movements. Local movements suggested by variable occurrence in particular areas. Records in Peninsular Malaysia and Singapore refer either to vagrants or to escaped captives.
Status and Conservation. Not globally threatened. Fairly common to common in most of range; rare within tiny range in China. Has adapted well to man-modified habitats. Nominate race is a rare exotic in Taiwan, where it has not managed to become established.
Bibliography. Chen Fuguan *et al.* (1998), Feare & Craig (1998), Lekagul & Round (1991), Lin Rueyshing (2001), McCarthy (2006), Rasmussen & Anderton (2005a, 2005b), Robson (2000), Smythies (1986), Sontag (1998), Stuart Baker (1926), Wells (2007).

65. Black-winged Myna

Acridotheres melanopterus

French: Martin à ailes noires **German**: Schwarzflügelmaina **Spanish**: Miná Alinegro
Other common names: Black-winged/White-breasted Starling

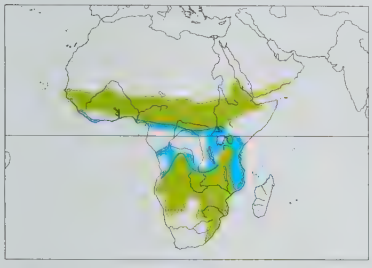
Taxonomy. *Gracula melanoptera* Daudin, 1800, "Inde" = Western Java.
Sometimes placed in genus *Sturnus*, but appears behaviourally and vocally closer to present genus. May form a superspecies with *A. burmannicus*. Three subspecies currently recognized.
Subspecies and Distribution.
A. m. melanopterus (Daudin, 1800) – Java (except SE part) and Madura I.
A. m. tricolor (Horsfield, 1821) – SE Java (E of Tosari).
A. m. tertius (E. J. O. Hartert, 1896) – Bali (including Nusa Penida) and Lombok.
Introduced (nominate race) in Singapore.

Descriptive notes. 23 cm. Small myna with striking black-and-white plumage; feathers of forehead, crown and nape hackled, and nape feathers elongated to form erectile crest. Nominate race is white, except remiges, which are black with bronze-green gloss (white bases to primaries), and tail, which is black with white tips, latter broader towards outer rectrices; iris dark brown, bare yellow skin around eye extending in small triangle behind eye; bill yellow, usually with darker, greyish base and gape; legs fleshy-yellow to pinkish-flesh. Sexes alike. Juvenile has grey crown to back. Races variable; *tricolor* has back grey, and largely black upperwing-coverts; *tertius* has grey mantle to uppertail-coverts, and extensively black upperwing-coverts. Voice. Flight call a high-pitched whistle, "tsoowit"or "tsoowee"; alarm a harsh "kaar". Disyllabic "kishaa kishaa" frequent from feeding birds; duet between apparent members of a pair. Also repeated "cha cha cha" with downward inflection on each note, throaty "chok", and other whistles and squawks. Calls resemble those of *A. tristis* and *A. javanicus*.
Habitat. Cultivated lands, fallow fields, grazing land, lawns and orchards, to c. 1300 m; recorded in E Java locally to 2400 m. Formerly in primary and secondary monsoon forests, as well as open savanna areas in lowlands, and suburban areas.
Food and Feeding. Diet fruit, nectar and insects. Mantids (Mantodea) recorded, also nectar of *Pithecellobium dulce*, and fruits of *Fagraea fragrans*, *Eugenia longiflora*, *Morus indica*, *Manilkara kauki*, *Passiflora foetida* and *Strychnos ligustrina*. Forages in trees, and on the ground in grassland and on beach. In pairs and small flocks. Roosts communally in tall trees, sometimes with *Leucopsar rothschildi*, and forms pre-roosting assemblies.
Breeding. Season Jan and Mar–May in W Java; recorded in Feb in most of Bali, but Jun in E of island. Presumed monogamous; this supported by evidence of duetting by pair-members. Nest in hole in rock or tree; one nest-hole lined with twigs. Clutch 3–4 eggs, plain sky-blue. No other information.
Movements. Presumed resident; local movements in response to flowering and fruiting of forest trees.
Status and Conservation. ENDANGERED. Rare and local; has declined since at least 1960s. Status on Lombok uncertain; very few records, and these may refer to vagrants or perhaps to escaped cagebirds. Very few records also from Madura. Formerly common; rapid recent decline appears to be consequence of unsustainable exploitation for cagebird trade; pesticides in agricultural areas also a possible threat. In survey undertaken in 2001 of 33 locations with historical records of this species, total of only 32 individuals found (at three sites), and absent at 30 sites. On Bali, originally concern over this species as possible competitor for *Leucopsar rothschildi*; it seems now, however, to have taken the place of latter as the species most frequently captured for cagebird trade. Has been nominally protected under Indonesian law since 1979. Occurs in at least three protected areas: Baluran National Park and Pulau Dua Reserve, in Java, and Bali Barat National Park, in Bali (maximum of 24 individuals). Breeding population in Singapore, thought to be derived from escaped cagebirds, is now apparently extinct.
Bibliography. Anon. (2008b), Butchart & Stattersfield (2004), Coates & Bishop (1997), Collar *et al.* (2001), Feare & Kang Nee (1992), Hails (1987), Harrison (1963b), Hoogerwerf & Hellebrekens (1967), Hoogerwerf & Rengers Hora Siccama (1938), Mees (1996), Morrison (1980), Rensch (1930, 1931), Robson (2000), Sieber (1978), Sody (1930), Stattersfield & Capper (2000), Trollope (1987), Wells (2007), White & Bruce (1986), de Wiljes (1957).

PLATE 44 ➤

PLATE 44

inches 4



Genus *CINNYRICINCLUS* Lesson, 1840

66. **Amethyst Starling**

Cinnyricinclus leucogaster

French: Étourneau améthyste **German**: Amethystglanzstar **Spanish**: Estornino Amatista
Other common names: Plum-coloured/Violet(-backed) Starling

Taxonomy. *Turdus leucogaster* Boddaert, 1783, no locality = Benin.
Genus possibly close to *Pholia*. Three subspecies recognized.
Subspecies and Distribution.
C. l. leucogaster (Boddaert, 1783) – breeds from Senegal E, S of Sahara and N of equator, to Sudan, possibly also Eritrea, Ethiopia and NW Somalia; non-breeding also in coastal areas, Gabon, PRCongo and N DRCongo, and S to Kenya.
C. l. arabicus C. H. B. Grant & Mackworth-Praed, 1942 – breeds S Arabian Peninsula (S Yemen E to SW Oman); probably also Eritrea, Djibouti, N Ethiopia, E Sudan and NW Somalia.
C. l. verreauxi (Bocage, 1870) – breeds from S DRCongo and Angola S to C Namibia and, in E, from S Kenya and W Tanzania S to Botswana, NE South Africa, Swaziland and Mozambique; in non-breeding season more widespread.

Descriptive notes. 16 cm; 33–56 g. Male nominate race has head and upperparts, including upperwing-coverts and tail, iridescent purple, in fresh plumage with strong blue overtone (with wear, coppery-plum colour predominates); purple primaries less iridescent, and when worn appear dark brown; chin, throat and upper breast iridescent purple, lower breast, belly, flanks, thighs and undertail-coverts pure white; iris has yellow outer ring, dark inner ring; bill and legs black. Female is very different from male, lacks any iridescence; crown, nape and side of head brown with dark central streaks on feathers, mantle to rump and tail dark brown with paler feather margins; wing dark brown, paler margins on coverts and secondaries, rufous on inner webs of primaries; chin, throat and underparts white with dark central streaks, broadest on breast; bare parts as for male. Juvenile resembles female, but has broader rufous feather edges, iris dark brown, bill and legs brown. Race *verreauxi* is larger than nominate, male has white base of outermost rectrix; *arabicus* male is very like nominate, female has almost plain brown upperparts lacking pale feather edgings. Voice. Song a varied phrase of up to 15 twanging notes and piping sounds; male sings near nest while female incubating or brooding; captive female sang varied song, including imitations of human whistles and calls of other birds in aviary. Contact calls are soft whistles and piping calls, unlike vocalizations of other glossy starlings (e.g. *Lamprotornis*).
Habitat. Open woodland areas and riverine woodland, to 2200 m in Malawi and recorded to 3000 m in Kenya; may occur around clearings in lowland forest, and on forest edge and in agricultural areas, as in E Usambaras, in Tanzania.
Food and Feeding. Mainly frugivorous, but insects also taken. Fruits eaten include those of *Celtis*, *Carissa edulis*, *Euclea divinorum*, *Apodytes dimidiata*, *Canthium lactescens*, *Clerodendron myricoides*, *Rhus*, *Zizyphus*, *Ficus*, *Lannea*, *Boscia pechuelli*, *Loranthus*, *Rotheca myricoides*, *Tapinanthus leendertziae*, *Morus*. Insects recorded include alate termites (Isoptera) and winged ants (Formicidae). In captivity, adults fed young entirely with live food. Hawks insects in air; some insects gleaned from branches. Important dispersal agent of the mistletoe *Phragmanthera dschallensis* in South Africa, regurgitating seeds after feeding. Forages primarily in trees; unlike many other starlings, spends little time on the ground, even in captivity. In pairs and in flocks; often associated with *Lamprotornis chalybaeus* and sometimes *Creatophora cinerea* in Kenya, and occasionally forages with mixed-species flocks of insectivores in trees.
Breeding. Season Mar–May in W Africa; Mar–Apr in Arabian Peninsula; Mar–Jul in Kenya, Nov–Dec in Tanzania; in DRCongo Aug–Oct in N and Jul–Nov in SE; Oct–Nov in Zambia and Malawi; Oct–Jan in S Africa, later (peak Feb–Mar) in Namibia. Monogamous. Nest 2–6 m above ground in tree hole, including old hole of woodpecker (Picidae), sometimes in hollow fence post, hole lined by both sexes, commonly with dung (donkey, horse and elephant dung recorded) and green leaves (*Euclea divinorum* at a nest in Kenya, *Olea* at one in South Africa); in captivity, used only leaves as lining in nestbox, and sometimes added leaves even during nestling period. Clutch 2–4 eggs, most often 3, eggs pale blue with fine purplish spots, more heavily spotted at thick end; incubation by female alone, period 12–14 days; chicks fed by both parents, one record of two males and one female feeding chicks (but no evidence that co-operative breeding a regular occurrence), nestling period c. 21 days. Brood parasitism by Lesser Honeyguide (*Indicator minor*) recorded; possibly also host to Greater Honeyguide (*Indicator indicator*) in Kenya.
Movements. Migratory in many regions, some populations apparently resident. In S of range almost entirely a breeding migrant S of R Okavango and R Zambezi, with virtually no overwintering; farther N, either some move only locally or breeding population replaced by birds from other areas. In Zambia, generally much less common winter months of Apr–Aug, but at some sites (e.g. Livingstone) most common during these months, suggesting that both breeding and non-breeding populations present within country; movements here primarily N–S. N of equator, no confirmed breeding in Sudan, Ethiopia and Eritrea, and only one probable breeding record from Somalia; non-breeders in this region could represent S breeders moving N, or migrants which bred in Arabian Peninsula, or birds from farther W. Within W Africa evidence of N–S movements in Nigeria, Ghana, Togo, Benin and Burkina Faso, but in some areas (e.g. coastal Nigeria) the species is considered resident. Breeding and movements likely to be determined by local rainfall regime and subsequent availability of fruit. Vagrant recorded in S Israel.
Status and Conservation. Not globally threatened. Widespread and generally common to locally abundant. In S of range, numbers in Kruger National Park, in South Africa, where a summer breeding migrant, estimated at more than 32,000 individuals; minimum of 20,000 estimated for C & S Mozambique.

Bibliography. Genus *HARTLAUBIUS* Bonaparte, 1853

67. **Madagascan Starling**

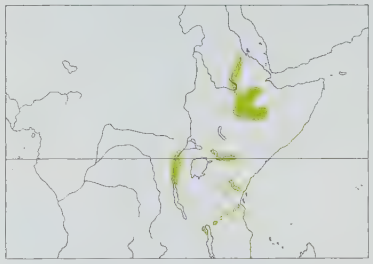
Hartlaubius auratus

French: Étourneau malgache **German**: Madagaskarstar **Spanish**: Estornino Malgache

Taxonomy. *Turdus auratus* Statius Müller, 1776, Madagascar.
Genus often subsumed into *Saroglossa*. Monotypic.
Distribution. Coastal areas of Madagascar (except arid SW corner).

Descriptive notes. 20 cm; 40 g. Distinctive starling with outermost rectrices longer than others, producing forked tail. Male has dark chocolate-brown head, rest of upperparts lighter brown; wing dark blue with some violet gloss, broad white strip on outer web and oval white patch on inner web of six outermost primaries, also white outer web on alula; tail dark blue-green with some gloss, outermost feathers with white outer web; below, brown of head extends as bib-shaped area to centre of breast; breast and flanks otherwise dark chocolate-brown, centre of belly, thighs and undertail-coverts white; iris brown; bill and legs black. Female has plumage pattern like male's but less glossy; crown and nape brown with pale feather edges, chin to chest and flanks grey-brown with dark central streaks on individual feathers. Juvenile resembles female. Voice. High-pitched "chee chreetee" song from conspicuous perch, given for minutes at a time, the only vocalization described.
Habitat. Humid areas with woodland; also regularly on fringes of clearings and cultivated areas near human activity. Below 1800 m.
Food and Feeding. Diet mainly fruit (according to stomach contents); also insects and nectar. Recorded food items are figs (*Ficus*), also berries; several seen to feed on bee larvae (*Apis*) at damaged bee hive. Often forages in treetops. Feeds in small flocks of 4–22 individuals, sometimes in company of other frugivores such as Madagascar Green-pigeon (*Treron australis*); rarely joins mixed-species flocks of insectivores.
Breeding. Season Sept–Nov, according mainly to gonadal development of specimens. Nest in tree hole. Eggs pale blue with rusty-brown spots. No other information.
Movements. Presumed to move locally in relation to fruiting cycles of plants; observations indicate periodic occurrence in many areas where not reported often.
Status and Conservation. Not globally threatened. Widespread and relatively common, even in modified habitats and near villages and cultivated areas. Poorly known for a species which is frequently encountered by biologists. Malagasy name (*Vorontainaomby*) reflects association with cow dung, implying a familiar bird which forages for insects at dung pats.
Bibliography. Benson *et al.* (1977), Feare & Craig (1998), Goodman, Pidgeon *et al.* (1997), Langrand (1990), Milon *et al.* (1973), Rand (1936), Steinbacher (1972).

Genus *ONYCHOGNATHUS* Hartlaub, 1849



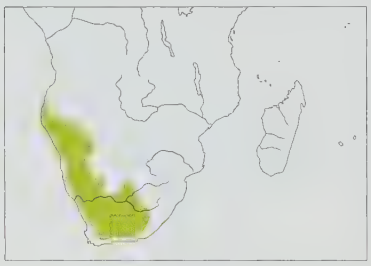
68. **Slender-billed Starling**

Onychognathus tenuirostris

French: Rufipenne à bec fin **German**: Zimtflügelstar **Spanish**: Estornino Picofino
Other common names: Slender-billed Red-winged Starling

Taxonomy. *Lamprotornis tenuirostris* Rüppell, 1836, Ethiopia.
Proposed race *theresae* (described from N Aberdares, in Kenya) considered largely inseparable from birds in rest of species' range. Treated as monotypic.
Distribution. Extreme SC Eritrea S to C & S Ethiopia; E DRCongo, SW Uganda, Rwanda and Burundi; Mt Elgon (Uganda–Kenya border) and W & C Kenya; NE & S Tanzania (Eastern Arc Mts); and NE Zambia and N Malawi (Nyika Plateau).
Descriptive notes. 25–30 cm; 127–142 g. Dark starling with rufous in wing, long sharply graduated tail. Male has crown, nape and chin black with greenish gloss, upperparts and entire underparts purple-black; upperwing black with greenish gloss, primaries reddish-brown with broad band of black at tip (in flight, wing patch appears centrally positioned); tail black with greenish gloss; iris hazel-brown; bill black, often pale tip; legs black. Female differs from male in having crown, nape, side of head, chin and throat duller greenish-black with grey feather tips, upperparts dull black, and underparts dull black with broad grey crescents at feather tips, producing scalloped

On following pages: 69. Pale-winged Starling (*Onychognathus nabouroup*); 70. Red-winged Starling (*Onychognathus morio*); 71. Neumann's Starling (*Onychognathus neumanni*); 72. Bristle-crowned Starling (*Onychognathus salvadorii*); 73. Somali Starling (*Onychognathus blythii*); 74. Socotra Starling (*Onychognathus frater*); 75. Tristram's Starling (*Onychognathus tristramii*); 76. White-billed Starling (*Onychognathus albirostris*); 77. Waller's Starling (*Onychognathus walleri*); 78. Chestnut-winged Starling (*Onychognathus fulgidus*).



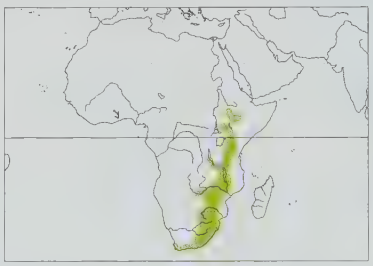
effect. Juvenile is dull sooty black, with bluish wash on wings and tail. Voice. Song, often in chorus, consists of whistles and harsher notes. Flight call a high-pitched "pleek"; sustained harsh whistling and chattering in flocks, reminiscent of parrots (Psittacidae).
Habitat. Inhabits montane forest from 1500 m to 3000 m, ranging up into alpine moorland zone as high as 5000 m; also descends to cultivated areas below forest. Breeds mostly at 1300–2300 m.
Food and Feeding. Diet primarily fruit; also nectar, and some invertebrates. Fruits taken include those of *Trema*, *Alongium*, *Sapium ellipticum*, *Schefflera goetzenii*, *Podocarpus milanjianus*, *Urera hypselodendron*, *Olea africana*, *Prunus africanus*, *Ocotea michelsonii*, *Ilex mitis*, *Macaranga neomildbreadiana*, *Polyscias fulva*, *Allophylus abyssinicus* and *Maesa lanceolata*. Takes nectar from *Lobelia* flowers, and may contribute to pollination. Small snail (Gastropoda) and pupae of blackflies (Simuliidae) found in stomach contents. Forages in trees, stretching to reach fruit clusters more than do other starling species. Hawks insects in flight; forages on wet boulders along streams. Often in flocks; large flocks of 50–100 individuals visit fruiting trees. In Ethiopia associates with *O. blythii*, elsewhere also with *Pholia sharpii*.
Breeding. Season Dec–Jan in Ethiopia, Dec in Ruwenzori region of SW Uganda, Jan–Mar and Aug–Dec in Kenya and Tanzania, and Sept–Dec in Zambia and adjoining Malawi; timing possibly related to water levels in mountain streams; sometimes double-brooded. Monogamous. Solitary or in small colonies. Nest built by both sexes, a mud base with moss, lined with grass, placed on ledge of rock face along mountain stream, often in cave under waterfall; same site used in successive years. Clutch 2–4 eggs, pale blue with fine red-brown spotting; incubation by female only, fed on nest by male, period 13 days; chicks fed by both sexes, brooded by female alone, nestling period c. 23 days. In one year 12 eggs produced only one fledgling; in another year 13 eggs produced six flying young.
Movements. Presumed mostly resident; extensive altitudinal movements and some local wandering.
Status and Conservation. Not globally threatened. Locally common to very common; uncommon to scarce in Eritrea (Senafe and Guna Guna region).
Bibliography. Amadon (1956), Benson (1946b), Brown (1965), Carswell *et al.* (2005), Chapin (1954), Dowsett *et al.* (2008), Dowsett-Lemaire (1983a, 1990), Fry *et al.* (2000), Lynes (1934), Moermond (1992), Moermond *et al.* (1993), Ogilvie-Grant (1910), Prigogine (1971), Young (1982).

69. Pale-winged Starling

Onychognathus nabouroup

French: Rufipenne nabouroup **German**: Fahlflügelstar **Spanish**: Estornino Naburup

Taxonomy. *Sturnus nabouroup* Daudin, 1800, Kamies Mountains, Namaqualand, South Africa.
Proposed race *benguellensis* described (from Benguela, in W Angola) on basis of shorter wing, but differences from birds in rest of species' range considered trivial. Treated as monotypic.
Distribution. SW Angola, Namibia (except E) and W interior of South Africa (E to S Free State and W Eastern Cape).



Descriptive notes. c. 27 cm; 94–122 g. Plumage is uniformly glossy black, except for narrow pale rufous panel visible on folded wing, some whitish of central primaries often visible; all primaries broadly tipped black, the inner five otherwise creamy-white, the outer four creamy-white on inner web and rufous-brown on outer (in flight, white patch appears centrally positioned in wing); iris orange-yellow; bill and legs black. Sexes alike. Juvenile is less glossy than adult, iris brown. Voice. Song of male a varied warbling, reminiscent of that of *Lamprotornis nitens*. Both sexes give warbling calls when perched. Flight call a ringing "preeoo"; alarm a harsh "churr" (the only call resembling equivalent *O. morio* vocalization).
Habitat. Arid country, from semi-desert to desert conditions, also entering towns to forage; from sea-level to 2000 m. Activities centred on rocky outcrops or cliffs, where roosting and nesting take place.
Food and Feeding. Diet fruit and arthropods; also nectar from *Aloe ferox*. Fruit of *Phoenix reclinata*, *Diospyros lycioides*, *Cussonia paniculata*, *Lycium*, *Heeria insignis*, *Ficus*, *Boscia albitrunca*, *Cotoneaster salicifolia*, *Crotalaria steudneri*, *Olea africana*, *Rhus lancea*, *Zizyphus mucronata*. Ticks (Acarina) taken, also insects such as alate termites (Isoptera), grasshoppers (Orthoptera), butterflies and caterpillars (Lepidoptera), beetles (Coleoptera). Enters towns to feed on date palms. Insects caught on ground, hawked in air or gleaned from vegetation. In Namibia and South Africa, regularly perches on klipspringers (*Oreotragus oreotragus*) and grooms ectoparasites from them, tolerated by the antelope; removes ticks also from both Cape mountain (*Equus zebra*) and Hartmann's mountain zebras (*Equus hartmanni*), and from desert-dwelling giraffes (*Giraffa camelopardalis*) in Namibia. In pairs and small groups.
Breeding. Season Nov–Apr in Namibia and Oct–Mar in South Africa; may be double-brooded. Monogamous; partners appear to remain together over several seasons. Semi-colonial, several pairs nesting on same cliff. Nest built by both sexes, from dry sticks wedged across rock cleft, with bowl of dry grass, animal hair and, in one case, needle-like leaves of *Parkinsonia africana* (no mud used), placed in crevice (usually a vertical cleft) in rocks; rarely, similar site in building utilized. Clutch generally 3 eggs, pale greenish, spotted and smudged with red-brown markings; incubation by female, male perches nearby (and often sings for extended periods), period 13–14 days; chicks fed by both male and female, nestling period c. 25 days. Nests regularly parasitized by Great Spotted Cuckoo (*Clamator glandarius*); will attack cuckoos near nests.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Common to abundant over wide range in sparsely populated regions.
Bibliography. Craig (1983c, 1988b, 1997j), Craig & Hulley (1992), Craig *et al.* (1989, 1991), Dean (2000b), Fennessy (2003), Fry *et al.* (2000), Hockey *et al.* (2005), Hulley *et al.* (2002), Jensen & Jensen (1969), Joubert (1972), Jubb (1980a), Kemp *et al.* (1972), Kok & van Ee (1990), Macdonald (1957), Penzhorn (1981), Penzhorn & Horak (1989), Steenkamp & Bridgeford (2002), Tilson (1977).

70. Red-winged Starling

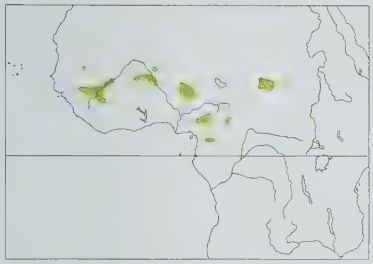
Onychognathus morio

French: Rufipenne morio **German**: Rotschwingenstar **Spanish**: Estornino Alirrojo
Other common names: Redwing/African Red-winged Starling

Taxonomy. *Turdus morio* Linnaeus, 1766, Cape of Good Hope, South Africa.
Has been thought to form a superspecies with *O. tristramii*. Sometimes treated as conspecific with *O. neumanni*. Two subspecies recognized.
Subspecies and Distribution.
O. m. rueppellii (J. Verreaux, 1856) – S Sudan, N Kenya and C Ethiopia; perhaps also NE Uganda.
O. m. morio (Linnaeus, 1766) – E Uganda, C Kenya, Tanzania, E DRCongo, E & S Zambia, Malawi, Zimbabwe, W Mozambique, E Botswana, and E & S South Africa.

Descriptive notes. 30 cm; 115–155 g. Dark starling with rather long, pointed tail. Male plumage is glossy black with inky-blue sheen, except for rufous patch visible on folded wing; all primaries chestnut-brown with short black tips (in flight, large rufous area in wing); iris dark red; bill and legs black. Female is like male, except that crown, nape, side of head, chin, throat and upper breast are ash-grey with some darker streaks (close to feather margins). Juvenile resembles male but less glossy, iris dark brown, bill brown. Race *rueppellii* is larger than nominate, with proportionately longer tail (longer than wing). Voice. Song a complex of pure, musical whistles and warbling notes; both sexes sing, some elements sex-specific, others shared; very few notes unique to an individual. Contact call often a 2-note "tweetwoo"; harsh "charr" alarm, low "kwok-kwok" when attacking potential nest predators; flocks produce mixture of whistles and song phrases. Captive individual hissed and snapped mandibles in threat.
Habitat. Original habitat rocky outcrops, gorges and mountainous regions with access to well-vegetated feeding areas; now common in many urban areas. To 2500 m Ethiopia, and seen above 4000 m on Mt Elgon (Uganda); sea-level to 3000 m in South Africa. Generally avoids arid regions and lowlands of E coast.
Food and Feeding. Diet principally fruit, but almost omnivorous and highly opportunistic. Recorded items include arils of invasive alien *Acacia cyclops*; fruit of *Ficus glumosa*, *Carissa edulis*, *Euclea divinorum*, *Canthium latescens*, *Phoenix reclinata*, *Protorhus longifolia*, *Celtis africana*, *Commiphora harveyi*, *Schefflera umbellifera*, *Scutia myrtina*, *Melia azederach*, *Ficus thonningii*, *Trichilia emetica*, *Cinnamomum zeylanicum*, *Juniperus*, *Lycium*, *Rhus longispina*, *Cussonia paniculata*, *Cassytha ciliolata*, *Coploon compressum*, *Trema*, *Morus*. Nectar from *Agave sisalana*, several species of *Aloe*, *Erythrina caffra*, *Erythrina latissima*, *Schotia brachypetala*, *Salvia faricana-lutea*, *Leucospermum conocarpodendron*, *Mimetes fimbiifolius*, *Protea subvestita*. Large seeds such as those of *Diospyros pubescens*, *Scutia myrtina*, *Lucium campanulatum*, *Phoenix reclinata* and the exotic *Brachychiton acerifolium* are regurgitated; smaller seeds retained in the gut, and may thus be transported farther. Sometimes forages on fruit alongside baboons (*Papio*) and hornbills (Bucerotidae). Animal food includes carrion, frogs, lizards, freshwater crabs (Decapoda), scorpions (Scorpiones), solifugids, spiders (Araneae), sandhoppers (Amphipoda), millipedes (Diplopoda), snails (Gastropoda) and intertidal molluscs (Mollusca), ticks (Acarina); many insects, e.g. termites (Isoptera), ants, bees and wasps (Hymenoptera), grasshoppers (Orthoptera), stick-insects (Phasmida), butterflies and caterpillars (Lepidoptera), beetles (Coleoptera), cicadas (Cicadidae). Forages in trees and bushes, and on ground, where it hops; feeds in intertidal zone. Attracted to salt deposits in Kenya. Hawks insects, even after dark at floodlights. Large prey items often broken up at an "anvil" site near nest, and then delivered piecemeal to chicks. Regularly associates with klipspringers (*Oreotragus oreotagus*), from which it removes ticks, and may feed on secretions from preorbital glands of this antelope; also gleans ectoparasites from eland (*Taurotragus oryx*), Cape mountain zebra (*Equus zebra*) and impala (*Aepyceros melampus*); perches on sheep, which are apparently exploited only to flush prey, but when perched on cattle this species routinely removes ticks (particularly from ears and under tail). At car parks gleans insects from radiator grilles of vehicles, and scavenges food at picnic sites and outdoor restaurants. On University of Cape Town campus (South Africa), resident birds fly through indoor passageways to the dining halls, collect food from cafeteria trays, and fly out to eat it in the courtyards. Occurs in pairs and in small flocks. Pair may roost at nest-site; communal roosts of up to 500 or more individuals on cliffs, buildings or tall trees; sometimes roosts in reedbeds along with *Creatophora cinerea* or *Acridotheres tristis*, also with weavers (*Ploceus*) and even with Common Black-shouldered Kites (*Elanus caeruleus*). Anting recorded occasionally in wild birds.
Breeding. Season Apr and Oct in Ethiopia; all months except Jun–Jul (peak Nov–Dec and Mar) in E Africa; recorded Sept–Mar (mainly Nov–Jan) in Zambia, Nov–Dec in Malawi, and Sept–Mar in S Africa; commonly double-brooded. Monogamous; probably long-term pair-bond. Nest built by both sexes over about six days, base generally includes mud, with grass, rootlets and sticks, lined with grass or other material (e.g. horsehair, or variety of "non-natural" materials may be included), placed on ledge, typically on rock or cliff, now often on building (first records in South Africa in 1880), including sites such as roof above petrol pumps at busy service station; sometimes on leaf bases of palm; even on wreck of fishing trawler 200 m offshore; some nest-sites occupied for more than 35 years. Aggressive around nest-site, attacking both humans and domestic animals, and other bird species, including African Palm-swift (*Cypsiurus parvus*); killed adult Rock Martin (*Ptyonoprogne fuligula*) and a bat (Chiroptera), and nestlings of Familiar Chat (*Cercomela familiaris*). Clutch 2–4 eggs; incubation by female, fed on nest by male, rarely male may sit, period 13–14 days (reports of eggs hatching after 23–25 days require confirmation); chicks fed by both parents, also captive young fed by unrelated adults (primarily female) concurrently feeding own nestlings c. 200 m away; nestling period 22–28 days, in captivity 22–25 days. Brood parasitism by Great Spotted Cuckoo (*Clamator glandarius*) regular in some areas. Nests robbed by Pied Crows (*Corvus albus*) and African Harrier-hawk (*Polyboroides typus*); baboons (*Papio*) also significant nest predators.
Movements. Mainly resident. Nomadic flocks containing more than 200 individuals collect during non-breeding season; ringing recoveries indicate that some individuals move distances in excess of 100 km.
Status and Conservation. Not globally threatened. Wide-ranging, and abundant in many areas. Numbers in Kruger National Park, in South Africa, estimated at more than 4000 individuals, even though limited suitable habitat is available; maximum of 500 in adjacent S Mozambique. Has colonized and exploited human settlements, and expanded breeding range through use of buildings

as nest-sites. Unprotected in some regions of South Africa, owing to the damage which it inflicts on fruit crops.



Bibliography. Amadon (1956), Archer (1993), Beasley (1978, 1991), Bleher *et al.* (2003), Broekhuysen (1951), Brooke (1995), Brown, D. (2003, 2006), Brown, L.H. 71. Neumann's Starling

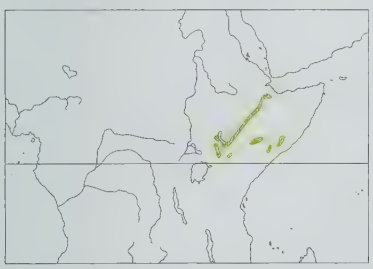
Onychognathus neumanni

French: Rufipenne de Neumann **German**: Neumannstar **Spanish**: Estornino de Neumann
Other common names: Neumann's Red-winged Starling, Crag Chestnut-winged Starling

Taxonomy. *Amydrus neumanni* Alexander, 1908, Petti, northern Nigeria.
Sometimes treated as conspecific with *O. morio*. Two subspecies recognized.
Subspecies and Distribution.
O. n. modicus Bates, 1932 – S Mauritania, E Senegal, NE Guinea, SW Mali, N Ivory Coast and SW Burkina Faso.
O. n. neumanni (Alexander, 1908) – E Mali, S Niger, N & SE Nigeria, N & S Cameroon, E Chad and adjacent W Sudan, and W Central African Republic.



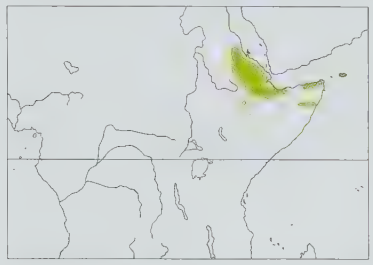
Descriptive notes. 25–30 cm. Large dark starling with long, graduated tail and heavy, deep bill. Male nominate race has uniformly glossy black plumage, except for narrowly black-tipped chestnut primaries; iris dark red; bill black; legs black. Female has crown, nape, side of head, chin, throat and upper breast ash-grey with some blue-black streaking; otherwise resembles male. Juvenile resembles male but duller. Race *modicus* is somewhat shorter-tailed than nominate, with tail shorter than wing length, iris brown. Voice. Low whistle from perched birds and musical "too-whee-oo" from nesting pair; melodious whistles reminiscent of those of orioles (*Oriolus*). Alarm a harsh "air air".
Habitat. Rocky outcrops, cliffs and inselbergs within Sahel zone; also around houses along R Niger. As low as 500 m in Nigeria; up to 2500 m in Sudan.
Food and Feeding. Diet mainly fruit, including figs (*Ficus*) and dates of palm *Phoenix reclinata*; possibly nectar of *Bombax*; insects such as ants (Formicidae); also small snails (Gastropoda), which are broken on an "anvil". In pairs and small flocks.
Breeding. Season Mar–Sept in Mali, Jun–Jul in Ivory Coast and Burkina Faso, Apr–May in Nigeria, Feb–Mar in Cameroon, and Jul–Aug in Sudan. Nest a simple cup of straw, placed on rock ledge in cave; nestlings fed by both parents. No other information.
Movements. Presumed resident; perhaps nomadic, as periodically absent from breeding areas in Cameroon, and flocks seen far from normal rocky habitats in Senegal.
Status and Conservation. Not globally threatened. Locally not uncommon; scarce in some areas. Wide range, but presence localized because of habitat requirements.
Bibliography. Bannerman (1948), Borrow & Demey (2001), Feare & Craig (1998), Fry *et al.* (2000), Morel (1985), Nikolaus (1987), Paludan (1936), Parelius (1967), Smith (1964).

72. Bristle-crowned Starling

Onychognathus salvadorii

French: Rufipenne de Salvadori **German**: Helmstar **Spanish**: Estornino de Salvadori

Taxonomy. *Galeopsar salvadorii* Sharpe, 1891, Turquel, Suk country, northern Kenya.
Monotypic.
Distribution. NW & S Somalia, C Ethiopia and N Kenya; possibly also E Uganda.



Descriptive notes. 40 cm; 160 g. Very large, dark starling with very long, graduated tail, and small "cushion" of bristly feathers on forehead (covering nostrils); also bristly feathers under chin and at corners of bill. Male is mostly dark inky black, with purple tone on head; primaries reddish-brown with black tips; tail has some greenish gloss; iris deep crimson; bill and legs black. Female resembles male, but tail shorter, has faint greenish gloss on head and throat, greyish feathers around eye and ear-coverts. Juvenile is duller than adult, with only faint gloss. Voice. Song consists of musical whistles, similar to those of *O. morio*; male sings from perch while female on nest. Chattering calls reminiscent of those of *O. tenuirostris*; alarm call a harsh "schwaah"; flight call a loud "swi-chit" or more subdued "weeo".
Habitat. Arid highlands, with cliffs and permanent water; may enter towns and gardens. Generally below 1300 m.
Food and Feeding. Primarily frugivorous; fruit and seeds reported in stomach contents. Forages in *Salvadora* bushes. In pairs and small flocks.
Breeding. Breeds Apr in Ethiopia, and May–Jun and Sept in Kenya; food-carrying adult in May in NW Somalia. Monogamous. Possibly in loose colonies in Somalia. Nest of sticks and grass, bound together with mud, placed in hole in cliff, sometimes alongside nests of congeners. No other information on wild-living individuals; in captivity, breeding successful when male excluded (previously chicks ejected from nest), but no further details provided.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Locally common in unpopulated montane regions; rather patchily distributed. Single record from Mt Moroto, in E Uganda.
Bibliography. Archer & Godman (1961), Ash & Miskell (1998), Benson (1946b), Brown (1965), Carswell *et al.* (2005), Ezra (1931), Feare & Craig (1998), Fry *et al.* (2000), Urban *et al.* (1970), Zimmerman *et al.* (1996).

73. Somali Starling

Onychognathus blythii

French: Rufipenne de Blyth **German**: Somalistar **Spanish**: Estornino Somalí
Other common names: Somali Chestnut-winged/Somali Red-winged Starling

Taxonomy. *Amydrus blythii* Hartlaub, 1859, Somalia.
Monotypic.
Distribution. Eritrea, Djibouti, NE & C Ethiopia and N Somalia; also Socotra I.

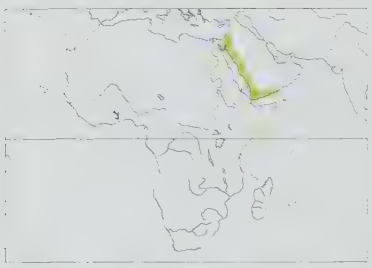
Descriptive notes. 28 cm; 100 g. Rather large, dark starling with long, graduated tail. Male plumage is mostly uniformly purple-black with some gloss; primaries reddish-brown with narrow black band near tip; iris reddish-brown; bill and legs black. Female differs from male in having crown, nape, side of head, chin, throat and breast plain ash-grey. Juvenile resembles male, but plumage duller, sooty brown, iris brown. Voice. Flight call high-pitched, musical "tleep"; harsh "scraich" alarm call; melodious and distinctive whistles also described as typical calls; "tee-tee" from flocks. Contact call of pair-members a disyllabic "di-heed".
Habitat. Primarily high mountains in arid regions, also rocky cliffs at lower altitudes. Breeds mostly above 1000 m, ranging to above 3000 m (to 3800 m in Bale Mts, in Ethiopia); down to sea-level in non-breeding season.
Food and Feeding. Diet mostly fruit and insects. Fruit of *Ficus*, *Juniperus*, *Olea* and *Dracaena cinnabari*; insects include beetles (Coleoptera), bees (Hymenoptera) and grasshoppers (Orthoptera). Nectar, and possibly pollen, of *Kniphofia* and *Lobelia* also taken. On Socotra, often perched on backs of cattle, benefiting from their flushing of prey; also removed ticks (Acarina) from the stock. Generally in small flocks of up to c. 20 individuals. Huge roosts reported occurring in deep gorges in Ethiopia.
Breeding. Season Apr in Eritrea, Apr–May and Sept in Ethiopia, and May in Somalia; Nov–Apr on Socotra on basis of presence of juveniles. Monogamous. Nest a loose structure of grass and feathers, apparently no mud, placed in hole in cliff or cave or in road embankment, sometimes on building, and even on ridge-pole of occupied tent. Clutch 4–5 eggs, greenish-blue with red speckling. No other information.
Movements. Resident, with some altitudinal movement. Seasonal visitor May–Jun to Bale Mts, in SC Ethiopia. Non-breeding visitor to coastal areas.
Status and Conservation. Not globally threatened. Common to locally abundant. Population on Socotra estimated at 33,000 individuals. Lives mainly in arid mountainous areas, where few direct threats. Occurs in several protected areas, e.g. Awash National Park and Bale Mountains National Park.
Bibliography. Archer & Godman (1961), Ash & Miskell (1998), Blanford (1870), Clouet *et al.* (1998), Fry *et al.* (2000), Gedeon & Neumann (2004), Ogilvie-Grant & Forbes (1903), Porter & Martins (1996), Ripley & Bond (1966), Ryan & Sinclair (1998), Smith (1957).

74. Socotra Starling

Onychognathus frater

French: Rufipenne de Socotra **German**: Sokotrastar **Spanish**: Estornino de Socotora
Other common names: Socotra Chestnut-winged/Socotra Red-winged Starling

Taxonomy. *Amydrus frater* P. L. Sclater and Hartlaub, 1881, Socotra.
Monotypic.
Distribution. Socotra.



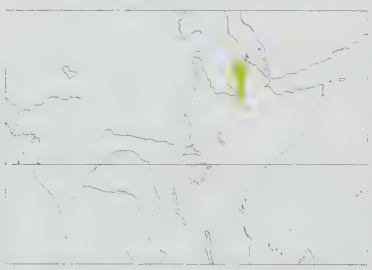
Descriptive notes. 25 cm; 100 g. Rather large, dark starling with fairly long, slightly graduated tail. Plumage is uniformly glossy black, except for reddish-brown primaries with dark brown tips; iris dark brown; bill dark brown; legs black. Sexes alike. Juvenile is sooty brown, with duller primaries, shorter tail, greyish bill. Voice. Most frequent call a clear, far-carrying whistle, "pee-hoo"; alarm a harsh "scraich"; contact call of partners a quiet monosyllabic "huid".
Habitat. Breeds and roosts in rocky areas; favours wooded areas for feeding, also visiting town gardens.
Food and Feeding. Diet mainly fruit and insects. Fruits recorded include those of *Ficus*, *Zizyphus* and *Dracaena cinnabari*; legume seeds also consumed. Insects such as ants (Formicidae) and grasshoppers (Orthoptera) taken; also snails (Gastropoda), which the starling breaks on "anvil" stones. Forages in manner of a *Turdus* thrush within vegetation, not on open ground nor in association with livestock; also enters settlements to feed on discarded scraps and refuse. In pairs and small groups.
Breeding. Nest-building and incubation observed in Nov; sightings of juveniles indicate breeding also Dec–Mar. Nest apparently a pile of grass and twigs, placed in natural cavity in roof or wall of limestone cave. No further information available. Adults are generally seen with only a single fledgling.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Socotra EBA. Population estimated at 12,000 individuals in 2003. Species' conservation status formerly rated as Vulnerable, but population currently stable, with no direct threats.
Bibliography. Clouet *et al.* (1998), Feare & Craig (1998), Fry *et al.* (2000), Gedeon & Neumann (2004), Ogilvie-Grant & Forbes (1903), Porter & Martins (1996), Ripley & Bond (1966).

75. Tristram's Starling

Onychognathus tristramii

French: Rufipenne de Tristram **German**: Tristramstar **Spanish**: Estornino de Tristram
Other common names: Tristram's Red-winged Starling, Tristram's Grackle

Taxonomy. *Amydrus Tristramii* P. L. Sclater, 1858, Mar Saaba, Hebron Valley, Israel.
Has been thought to form a superspecies with *O. morio*. Monotypic.
Distribution. E & S Israel, Palestine and W Jordan S to extreme NE Egypt (Sinai) and W Arabian Peninsula (S to Yemen).



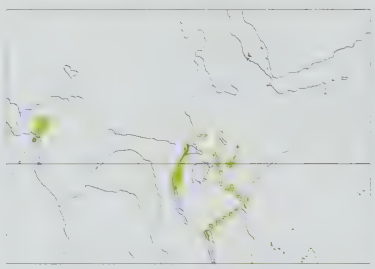
Descriptive notes. 25 cm; 115–131 g. Fairly large, dark starling with medium-length tail, rounded at corners. Male plumage is uniformly glossy black, except for reddish-brown primaries with black tips; iris very dark brown; bill blackish; legs black. Female has crown, nape, side of head, chin and throat grey, dark streaks on nape and lower throat; otherwise like male. Juvenile resembles adult male, but less glossy. Voice. Contact calls are musical whistles, e.g. "wuuwiiwuu"; harsh alarm call "veeeeh", reminiscent of that of *O. morio*. Series of soft squeaks and rasps possibly functions as song.
Habitat. Desolate rocky areas in deserts (apparently physiologically adapted to such conditions); also urban areas.
Food and Feeding. Diet mostly fruit and insects, occasionally small snails (Gastropoda), also household scraps. Fruits include those of *Ficus nitida*, *Atriplex semibaccata*, *Vitis*, *Myoporum*, *Coridia sinensis*, *Salvadora persica*, *Olea chrysophylla*, *Phoenix dactylifera* and hips of *Rosa abyssinica*. Insects include beetles (Coleoptera), grasshoppers (Orthoptera), flies (Diptera), butterflies (Lepidoptera) and bees (Hymenoptera). Also scavenges bread and dog biscuits from houses in town; those breeding outside urban areas may visit towns in order to forage. Plucks ticks (Acarina) from hides of ibex, donkeys and camels; regular grooming sites visited by Nubian ibex (*Capra ibex*) in Israel, with apparent mutual exchange of signals between bird and mammal. Reports that camels also groomed at regular sites. In pairs and small flocks; larger flocks, containing up to c. 100, outside breeding season. Roosts of several hundred (occasionally to 2000) individuals in non-breeding season.
Breeding. Breeds Mar–Jun in Israel; second broods common. Monogamous. Sometimes in loose colonies. During courtship male fed female with insects, also presented small twigs to her. Nest built by both male and female, made from grasses (no mud used) or, in urban habitat, from green tamarisk (*Tamarix*) branches and sometimes with leaves and feathers in bowl, placed in deep hole or crevice 6–21 m above ground in cliff or building; nest reused for second brood. Clutch 2–4 eggs, sky blue with scattered brown spots, concentrated at thicker end; incubation by female only, period 15–17 days; chicks fed by both parents, nestling period 28–31 days; young fed for about ten days after fledging. Infanticide noted after female lost mate while feeding chicks; replacement male killed chicks, and took over female and nest-site. In Israel, urban breeders produced average of 1·3–2·3 fledged young per pair.
Movements. Resident; also partly nomadic. Suggested that birds moved from low, hot summer breeding areas to cold N wintering areas, but no evidence of large-scale movements on seasonal basis.
Status and Conservation. Not globally threatened. Common to locally abundant. Estimated population in Israel c. 1000–2000 pairs in 1980s. Widespread in unpopulated regions, and now increasingly occupying man-modified environments. Has colonized urban areas, and now found both foraging and nesting in towns in many parts of range.
Bibliography. Amadon (1956), Bigger (1931), Cramp & Perrins (1994), Dmi'el & Tel-Tzur (1985), Gallagher & Woodcock (1980), Hofshi & Katzir (1990), Hofshi *et al.* (1987a, 1987b), Meinertzhagen (1954), Paz (1987), Shirihai (1996), Uhlig & Uhlig (1997), Yosef & Yosef (1991).

76. White-billed Starling

Onychognathus albirostris

French: Rufipenne à bec blanc **German**: Weißschnabelstar **Spanish**: Estornino Piquiblanco

Taxonomy. *Ptilonorhynchus* (*Kitta*) *albirostris* Rüppell, 1836, Ethiopia.
Monotypic.
Distribution. Highlands from S Eritrea S to C Ethiopia.



Descriptive notes. 25 cm; 130–145 g. Medium-sized, pale-billed dark starling with comparatively short tail; feathers in front of eye directed forwards along bill, covering nostrils. Male plumage is mostly glossy blue-black, with greenish gloss on wings and tail; primaries reddish-brown with narrow black tips; iris brown; bill white; legs black. Female differs from male in having crown, nape, side of head, throat and upper breast pale grey. Juvenile has dark head like male. Voice. Song intermediate between chatter and musical whistling; calls at nest repeated "kwit-kwit"; less melodious than voice of *O. morio*. Alarm call a harsh "charr".
Habitat. Rocky gorges and cliffs, between 2000 m and 3000 m; locally also in towns.
Food and Feeding. Diet fruit and insects. Fruit of *Ficus* and *Juniperus* eaten; insects include grasshoppers (Orthoptera), beetles (Coleoptera), butterfly (Lepidoptera), and winged ants (Formicidae) and other Hymenoptera. Feeds in trees; hawks insects in air. In pairs and small groups; larger flocks in non-breeding season. Communal roosts of more than 100 individuals outside breeding period.
Breeding. Breeds Aug–Oct in Ethiopia; nest-building in Jun in Eritrea. Monogamous. Nest in hole or crevice in rock, or on man-made structure, including bridge or building, sometimes on door lintel of derelict building; one nest made from grass and cereal-leaf blades, lined with plant fibres and rootlets (no mud used in construction); some nest-sites used for three successive years. Clutch 4 eggs, turquoise blue with small brown to blackish spots, mainly at thick end; incubation by female alone, chicks fed by both parents, male may bring food to female on nest; combined incubation and nestling periods estimated at 35 days. At three active nests, eight young fledged from minimum of twelve eggs.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Locally common to very common; uncommon in S of range (Bale Mts).
Bibliography. Brown & Thorogood (1976), Érard & Prévost (1971), Feare & Craig (1998), Fry *et al.* (2000), Smith (1957), Urban & Brown (1971).

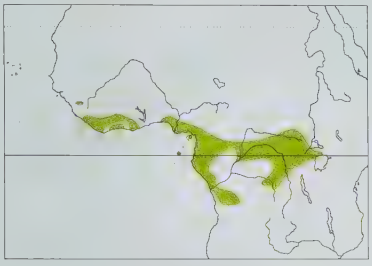
77. Waller's Starling

Onychognathus walleri

French: Rufipenne de Waller **German**: Wallerstar **Spanish**: Estornino de Waller
Other common names: Waller's Chestnut-winged/Waller's Red-winged Starling

Taxonomy. *Amydrus walleri* Shelley, 1880, Usambara Mountains, Tanzania.
Three subspecies recognized.
Subspecies and Distribution.
O. w. preussi Reichenow, 1892 – SE Nigeria (Obudu Plateau), W Cameroon and Bioko I (Fernando Póo).
O. w. elgonensis (Sharpe, 1891) – S Sudan, E DRCongo, SW Uganda, W Rwanda, W Burundi, and Mt Elgon (Uganda–Kenya border) and W Kenya (W of Rift Valley).
O. w. walleri (Shelley, 1880) – Kenyan Highlands E of Rift Valley, S through Tanzanian Eastern Arc to N Malawi.

Descriptive notes. 20 cm; 73–92 g. Relatively small, dark starling with shortish round-ended tail and red eyes. Male nominate race has crown dull blue-black, nape and ear-coverts glossy black with metallic green sheen; mantle, back and rump dull blue-black; wing and tail dull blue-black, primaries reddish-brown with broad black tips (in flight, wing patch appears centrally positioned); chin and throat glossy black with metallic green sheen; underparts dull blue-black; iris deep red; bill and legs black. Female differs from male in having crown, nape, side of head, chin and throat ash-grey, nape streaked with dark metallic green, breast to undertail-coverts dull charcoal. Juvenile resembles male but lacks gloss in plumage, iris dark brown. Race *elgonensis* is shorter-winged and with flatter, broader bill than nominate, female has grey on head and throat more restricted, crown to nape and throat with heavy streaking; *preussi* is like previous in plumage, but smaller. Voice. Song a series of clear whistled notes, also some chipping and scratchy elements. Sings in groups before separating out on breeding territories. Flight-intention call a 2-note whistle; contact call a single loud whistle; harsh, grating alarm call.
Habitat. Montane forest, including isolated patches, as well as forest edge and areas of shifting agriculture. Mainly at 1000–3000 m; down to 200 m on Bioko, and to 300 m in E Usambaras (Tanzania).
Food and Feeding. Diet fruit and animal items. Fruit includes that of *Cinnamomum zeylanicum*, *Juniperus*, *Symphonia*, *Ekebergia capensis*, *Prunus africanus*, *Ocotea michelsonii*, *Ocotea usambarensis*, *Ilex mitis*, *Macaranga neomildbreadiana*, *Macaranga kilimandscharica*, *Maesa*, *Sapium ellipticum*, *Rapanea*, *Urura*, *Podocarpus latifolius*, *Harungana*, *Schefflera*, *Alangium chinense*, *Polyscias fulva*, *Allophyllus abyssinicus*, *Ficus natalensis*, *Afrocrania volkensii*, *Aphloia theiformis*, *Bersama abyssinica*, *Bridelia brideliifolia*, *Bridelia micrantha*, *Celtis africana*, *Myrica salicifolia*, *Rhus longipes*, *Trichilia dregeana*, *Xymalos monospora*. Animal food taken includes chameleons (Chamaeleonidae), spiders (Araneae); also insects, including termites (Isoptera). Forages mostly in forest canopy. Adept at gripping thin branches and thus climbing to terminal clusters of fruit. Flying insects caught on the wing; insects also collected from bark, and gleaned from foliage. In pairs and small flocks; flocks of non-breeders can contain more than 50 individuals.
Breeding. Season Nov–Dec in Cameroon; Nov and possibly Mar–Apr in E DRCongo, May in Uganda, Aug–Sept in Kenya and Aug–Nov in Malawi. Monogamous, probably with long-term pair-bond. Nest a cup made from moss, bark and dead leaves, lined with thin twigs, liana fibres and bark, materials brought in by both male and female, placed in hole 4–20 m above ground in live or dead tree. Eggs described as uniform blue-green. No information on clutch size, but 1–3 nestlings noted; incubation by female, estimated period 13–16 days; chicks fed by both sexes, nestling period 23–30 days. Productivity apparently low; predation considered major source of nesting failure in Malawi, where single-brooded and most nests appeared to produce only a single fledgling.
Movements. Presumed resident; local wandering, perhaps involving primarily flocks of non-breeders. Possible altitudinal movements in E Tanzania.
Status and Conservation. Not globally threatened. Common in many areas of range. Estimated 12 pairs in 160 ha of forest on Nyika Plateau, in Malawi, in 1980–1981. Able to utilize isolated forest patches.
Bibliography. Amadon (1956), Bannerman (1948), Basilio (1963), Borghesio *et al.* (2008), Borrow & Demey (2001), Burgess & Mlingwa (2000), Carswell *et al.* (2005), Dowsett *et al.* (2008), Dowsett-Lemaire (1983a, 1983b, 1985, 1988, 1990), Dowsett-Lemaire & Dowsett (2006), Fry *et al.* (2000), Lack (1936), Moermond (1992), Moermond *et al.* (1993), Nikolaus (1987), Sclater & Moreau (1933), Taylor & Taylor (1988), Zimmerman *et al.* (1996).



78. Chestnut-winged Starling

Onychognathus fulgidus

French: Rufipenne de forêt **German**: Kastanienflügelstar **Spanish**: Estornino Alirrufo
Other common names: Common Chestnut-winged/Forest Chestnut-winged Starling

Taxonomy. *Onychognathus fulgidus* Hartlaub, 1849, São Tomé.
Races sometimes treated as two separate species. Notable variation, but much local overlap prevents meaningful classification into more than one mainland subspecies: birds E & S from Cameroon sometimes separated as race *intermedius*, supposedly intermediate in size between nominate and *hartlaubii* and with more bluish iridescence on head; birds of Upper Guinea previously separated as race *harterti*; name *hartlaubii*, with type locality of Bioko, thus variously applied to groups of W or E, or, as here, to all mainland populations; proposed race *leoninus* (Sierra Leone) included within *hartlaubii*. Two subspecies currently recognized.
Subspecies and Distribution.
O. f. fulgidus Hartlaub, 1849 – São Tomé I, in Gulf of Guinea.

O. f. hartlaubii Hartlaub, 1858 – S Guinea, N & S Sierra Leone and Liberia E to Ghana, S Nigeria, and S Cameroon S, including Bioko I (Fernando Póo), to N Angola (E to NW Lunda Norte) and E to S Sudan (Begengai), W Uganda and NE & EC DRCongo.

Descriptive notes. 28-35 cm; 103–140 g. Large, dark starling with long, graduated tail and long, heavy bill. Male nominate race has crown glossy blue-black, nape, ear-coverts, side of head, chin and throat black with greenish gloss; mantle and back black with greenish gloss, rump with purple tone; wing and tail black with greenish gloss, primaries reddish-brown with broad black band at tips (in flight, patch appears to be centrally positioned in wing); underparts purple-black; iris red; bill black; legs black. Female differs from male in having crown, nape, chin, throat and side of head grey, heavily streaked with glossy dark green. Juvenile is duller version of male, with brown iris. Race *hartlaubii* is much smaller than nominate, with notably smaller bill, has greenish sheen on head and neck of male. VOICE. Song a mixture of low, glottal and high screechy notes, also a grating "churng-chuzick". Flight call a whistled "ti-ew", also other disyllabic variants; harsh alarm call; seldom calls when perched.

Habitat. Lowland primary forest and old secondary forest, sometimes in clearings and wooded gardens; generally below 1000 m, but frequently near hills.

Food and Feeding. Diet mainly fruit; also nectar of *Bombax*, and insects. Fruit of *Dacryodes*, *Ficus*, *Uapaca*, *Cecropia*, *Pycnanthus*, *Guibourtia*, *Trichoscypha*, *Maesopsis eminii*, *Elaeis guineensis*. Insects such as alate termites (Isoptera), beetles (Coleoptera) and winged ants (Formicidae) recorded as taken. Forages mostly in canopy; hawks insects from branches. In pairs and small groups, mainly of fewer than ten individuals. On Bioko foraged in groups with *Lamprotornis splendidus*; elsewhere with latter species and also *Hylopsar cupreocauda* and *Hylopsar purpureiceps*.

Breeding. Season Oct–Mar in Liberia, Sept–Dec in Ivory Coast, Oct–Nov in Ghana, Jan–May in Nigeria, May–Jun in Cameroon, and Sept–Nov in São Tomé; in DRCongo, Apr–Sept in N, Nov and Mar–Apr in E (Itombe region); Sept in Uganda; in breeding condition in Aug in Angola. Nest in broad base of palm fronds, among massed epiphytes or in tree hole 15–35 m above ground, sometimes in nest base of Red-necked Buzzard (*Buteo auguralis*) or of Palm-nut Vulture (*Gypohierax angolensis*), and once in underside of Crowned Hawk-eagle (*Stephanoaetus coronatus*) nest; in Liberia often near colony of Yellow-mantled Weavers (*Ploceus tricolor*); nest-site may be used in consecutive years. No other information.

Movements. Resident, but appears to be highly mobile; outside breeding season, seldom at one site for more than a few days. In Ivory Coast, pattern of occurrence suggests local seasonal migration.

Status and Conservation. Not globally threatened. Widespread, and locally common. Fairly common in W Africa; reported also from Misahöhe, in Togo, but status in that country unclear. Locally common in N Angola.

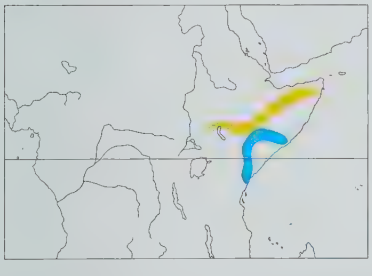
79. Hildebrandt's Starling

Lamprotornis hildebrandti

French: Choucador de Hildebrandt **Spanish**: Estornino de Hildebrant
German: Hildebrandtglanzstar

Taxonomy. *Notauges Hildebrandti* Cabanis, 1878, Ukamba, Kenya.
May form a superspecies with and formerly considered conspecific with *L. shelleyi*; both have sometimes been combined in a superspecies with *L. pulcher*. Monotypic.
Distribution. NC Kenya S to NC Tanzania.



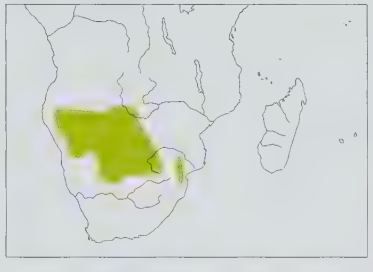
Descriptive notes. 18 cm; 50–69 g. Has forehead and crown dark glossy blue, half-collar of bronze-green on nape; upperparts dark glossy blue; wing bronze-green, lesser and median coverts blue with velvety-black subterminal spots, greater coverts with black terminal spots on inner feathers, primaries deep blue on outer webs (attenuated on primaries P5–P9, but no indentations on inner webs); tail glossy blue-green; chin, throat, ear-coverts and upper breast dark glossy purple, lower breast and upper belly light orange-buff, lower belly, flanks, thighs and undertail-coverts rufous; iris orange-red; bill and legs black. Sexes alike. Juvenile has dull charcoal-grey upperparts, some gloss on wings and tail, underparts pale chestnut-brown; iris brown, dull yellow eyering; bill dull orange-yellow. VOICE. Song a slow sequence of low notes "ch-rak ch-rak chee-chee-wee chee-wee rak rak rak" interspersed with whistles. Alarm call "chu-ee"; contact call in flocks a whistled "chule".
Habitat. Open thornbush country and open woodland between 500 m and 2200 m; also around cattle enclosures and settlements.
Food and Feeding. Diet probably mainly insects; beetles (Coleoptera) and grasshoppers (Orthoptera) noted; hawks alate termites (Isoptera). Seeds (possibly from fruit) in stomach contents; in Kenya, fed on fruit of *Carissa edulis, Euclea, Rhus, Apodytes dimidiata*. Forages primarily on ground; may make use of mammals, taking insects disturbed by these. In pairs and small flocks; often feeds in association with *L. superbus* and *L. chalybaeus*, sometimes with *Creatophora cinerea*, less often with other sturnids.
Breeding. Season Mar–May and Oct–Dec; on Laikipia Plateau, Kenya, May-Jul. Co-operative breeding reported, but species encountered primarily in pairs at one Kenya site. Nest a pad of hair or plant fibres placed in tree hole, generally old woodpecker (Picidae) hole, 1–10 m above ground, or hole in fence post, lamppost or telegraph pole used; competition for nest holes with *L. chalybaeus*. Clutch 3–4 eggs, reported as white, but possibly in error; no information on incubation and nestling periods; both sexes feed young. Nests parasitized by Great Spotted Cuckoo (*Clamator glandarius*).
Movements. Presumed resident, with no more than local movements; absent from breeding areas for several months in Kenya.
Status and Conservation. Not globally threatened. Fairly common to rather uncommon. Although sometimes regarded as uncommon, this species' habitat is not under threat, and it occurs within several protected areas.
Bibliography. Erlanger (1905), Feare & Craig (1998), Fry *et al.* (2000), Geertsema (1976), Lewis & Pomeroy (1989), Short & Horne (2005), Zimmerman *et al.* (1996).

80. Shelley's Starling

Lamprotornis shelleyi

French: Choucador de Shelley **German**: Shelleyglanzstar **Spanish**: Estornino de Shelley

Taxonomy. *Spreo shelleyi* Sharpe, 1890, Somalia.
May form a superspecies with and formerly considered conspecific with *L. hildebrandti*; both have sometimes been combined in a superspecies with *L. pulcher*. Monotypic.
Distribution. Breeds S Ethiopia and NW Somalia, probably also SE Sudan and N Kenya; non-breeding E Kenya and S Somalia.



Descriptive notes. 16 cm; 45 g. Has crown, chin, throat and upper breast glossy dark purple, matt black patch from lores to ear-coverts, narrow bronzy-green collar on nape; upperparts dark glossy blue; wing bronze-green, lesser and median coverts dark blue, black subterminal spots on lesser, median and greater coverts, primaries dark purple on outer webs (attenuated on primaries P6–P8, but lack indentations on inner webs); tail glossy blue-green; underparts from lower breast down uniformly dark rufous-brown; iris orange-red; bill and legs black. Sexes alike. Juvenile has charcoal-grey upperparts, some gloss on wings and tail, pale chestnut-brown underparts, iris brown or grey-blue. VOICE. Song of short phrases combining whistles, nasal calls and scratchy sounds, described as a melange of *L. superbus* and White-browed Sparrow-weaver (*Plocepasser mahali*) songs. Contact call a disyllabic or trisyllabic "jaraanh".
Habitat. Semi-arid bushed and wooded country, especially with *Commiphora*, from sea-level to c. 1300 m; generally below 1000 m in Kenya.
Food and Feeding. Few data. Perhaps more insectivorous than frugivorous; in Kenya, common along R Tana when *Salvadora* bushes fruiting. Forages on the ground less than do *L. superbus* and *L. hildebrandti*. In small flocks; outside breeding season, flocks of up to 100 and more individuals associate with nomadic *Speculipastor bicolor*.
Breeding. Season Mar–Apr in Ethiopia; Apr–Jun in Somalia, where may be double-brooded. Nest a lining of grass and feathers in tree hole or cleft 1·5–3 m above ground; in Ethiopia, also found in termite (Isoptera) mound. Clutch 3–6 eggs, pale blue, rarely speckled with brown; in captivity, incubation by female while male sang from nearby perch, chicks fed by both parents, nestling period 22–23 days. No other information.
Movements. Migratory; some perhaps sedentary within breeding areas. Moves N into Ethiopia and Somalia in Mar–Apr to breed; in Kenya, non-breeding visitor Oct–Mar. In Tsavo East National Park, in Kenya, recorded only in Nov and Feb–Mar, suggesting regular movements also within non-breeding range.
Status and Conservation. Not globally threatened. Locally common to very common within small breeding range. Appears to be rather uncommon in much of non-breeding range. Habitat occupied by this species is unsuitable for large-scale settlement or agriculture.
Bibliography. Archer & Godman (1961), Ash & Miskell (1983), Benson (1946b), Fry *et al.* (2000), Lack (1985), Lewis & Pomeroy (1989), Nikolaus (1987), Scamell (1964), Zimmerman *et al.* (1996).

81. Burchell's Starling

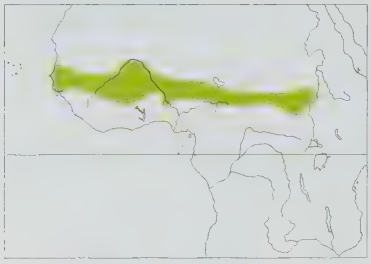
Lamprotornis australis

French: Choucador de Burchell **German**: Riesenglanzstar **Spanish**: Estornino de Burchell
Other common names: Burchell's Glossy/Greater Glossy Starling

Taxonomy. *Megalopterus australis* A. Smith, 1836, country north of Kurrichane, North West Province, South Africa. Monotypic.
Distribution. S Angola S to C & E Namibia, E to SW Zambia, NW Zimbabwe, Botswana, N South Africa and Swaziland.

Descriptive notes. 30 cm; 74–138 g. Comparatively robust with long, graduated tail, and dark eye. Has forehead and crown to mantle and back blue-green, distinct blue-purple sheen on nape (almost forming a collar on some individuals), rump and uppertail-coverts purple with bronzy tinge; ear-coverts and patch below eye bronze, fringed with blue, often appearing matt-black and, together with black lores, contrasting sharply with very glossy surrounding feathers; flight-feathers with blue-purple sheen and strong cross-barring, long, graduated tail violet with strong barring; chin, throat and breast blue-green, purple shading in centre of belly; flanks, thighs and undertail-coverts bluish; iris dark brown; bill and legs black. Contrasting dark mask and often partly exposed dark centres of upperwing-coverts and scapulars help to separate from *L. mevesii*. Sexes alike. Juvenile has matt black underparts, dull green sheen on upperparts. VOICE. Song an extended, harsh croaking with pauses between groups of notes; a throaty, musical call given by perched birds, perhaps as territorial display.
Habitat. Open woodland and savanna, avoiding miombo woodland; associated particularly with camelthorn trees (*Acacia erioloba*) or knobthorn (*Acacia nigrescens*). To 1500 m; below 500 m in E lowveld of South Africa.
Food and Feeding. Diet includes fruit, such as *Diospyros mespiliformis*, and flowers of *Acacia giraffae*; also animal food, ranging from small mice (Muridae) to centipedes (Chilopoda), locusts (Acrididae), beetles (Coleoptera), termites (Isoptera) and ants (Formicidae). Scavenges at picnic sites in national parks; attracted to balchatri traps baited with mice (traps set for raptors). Forages mainly on ground, walking with long strides; often alongside *L. nitens* and *L. chalybaeus*, or *L. mevesii*. In pairs and groups, sometimes in larger flocks; in non-breeding season, roosts of up to 1000 individuals in tall trees, also in reedbeds.
Breeding. Breeds Mar in Zambia, Jan–Apr in Namibia and Botswana, and Sept–Mar (mostly Oct–Jan) in South Africa. Monogamous. Nest built by both sexes, with grass, sometimes fresh green leaves, feathers, shed snakeskin, dry dung, also artificial material (string, cloth, paper, strips of plastic), placed 2–7 m above ground in tree hole, either natural hole or old hole of woodpecker (Picidae) or barbet (Capitonidae), or in rock crevice, building or even tower of windmill; nestbox accepted where available; hole often reused in successive years. Clutch 2–4 eggs, bright blue to greenish-blue, plain or with sparse reddish-purple spots; incubation by female only, period c. 15 days; chicks fed by both parents, nestling period 20–24 days. Brood parasitism by Great Spotted Cuckoo (*Clamator glandarius*) recorded in Namibia, Botswana and South Africa, but young of present species may be raised successfully alongside single cuckoo chick; nests occasionally parasitized by Greater Honeyguide (*Indicator indicator*).
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Locally common. Wide range in sparsely populated areas; common in some national parks. Population in Kruger National Park, South Africa, estimated at over 16,000 birds and that of Kgalagadi Transfrontier Park, on SW Botswana–South Africa border, at more than 4000. Reports of this species from Mozambique require corroboration.
Bibliography. Brooke (1967b, 1968a), Craig (2000), Craig & Herremans (1997b), Dean & Macdonald (1972), Dean *et al.* (1987), Dowsett *et al.* (2008), Fry *et al.* (2000), Hockey *et al.* (2005), Hoesch & Niethammer (1940), Hopkinson (1932), Kemp, Herholdt *et al.* (2001), Kemp, Kemp *et al.* (1972), McCarthy (2006), Parker (1999), Pickles (1989), Tarboton *et al.* (1987).

82. Long-tailed Glossy Starling



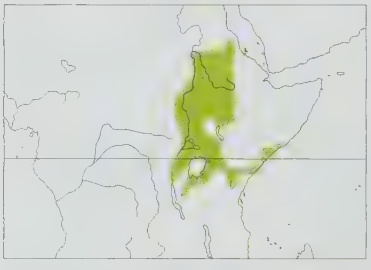
Lamprotornis caudatus

French: Choucador à longue queue **Spanish**: Estornino Colilargo
German: Langschwanz-Glanzstar

On following pages: 83. Rüppell's Glossy Starling (*Lamprotornis purpuroptera*); 84. Meves's Long-tailed Starling (*Lamprotornis mevesii*); 85. Ashy Starling (*Lamprotornis unicolor*); 86. Splendid Glossy Starling (*Lamprotornis splendidus*); 87. Principe Glossy Starling (*Lamprotornis ornatus*); 88. Golden-breasted Starling (*Lamprotornis regius*); 89. Superb Starling (*Lamprotornis superbus*); 90. Chestnut-bellied Starling (*Lamprotornis pulcher*); 91. African Pied Starling (*Lamprotornis bicolor*); 92. White-crowned Starling (*Lamprotornis albicapillus*); 93. Fischer's Starling (*Lamprotornis fischeri*).

Other common names: Supple-tailed Glossy Starling

Taxonomy. *Turdus caudatus* Statius Müller, 1776, Senegal.
Forms a superspecies with *L. purpuroptera* and *L. mevesii*. Monotypic.
Distribution. S Mauritania, Senegambia, Guinea-Bissau and N Guinea E in narrow band (semi-arid belt) to S Chad, N Central African Republic and W & EC Sudan.



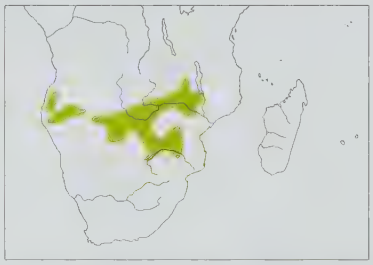
Descriptive notes. c. 40–50 cm, including tail of up to 33 cm; 103–133 g. Large glossy starling with extremely long, strongly graduated, supple tail, rectrices paired in step-like fashion. Has crown, side of head and chin blue-green with bronze sheen; nape, mantle and back have blue-green gloss, rump blue-violet with purple gloss; wing blue-green, prominent velvety-black spots near tips of scapulars and wing-coverts; tail purple with dark cross-barring; throat and breast glossed blue-green, belly, flanks, thighs and undertail-coverts blue-violet with central bronzy patch; iris creamy white; bill and legs black. Sexes alike in plumage, male clearly larger than female. Juvenile lacks gloss of adult, has dark iris for at least one year. Voice. Common call a sing-song "elekele", and coughing "chuc-chu-chu". Raucous alarm calls recognized by other species in foraging groups.
Habitat. Park-like savanna woodland, farmland, well-wooded residential areas, thorn-thickets and wooded hills surrounded by cultivation.
Food and Feeding. Diet fruit, such as *Azadirachta indica*, and insects, including terrestrial and winged ants (Formicidae) and alate termites (Isoptera). Forages mainly on ground, while hopping and walking; also in trees. In small flocks. In Senegal, apparent leader of mixed-species foraging groups which typically included Red-billed Hornbills (*Tockus erythrorhynchus*), Hoopoes (*Upupa epops*), Senegal Coucals (*Centropus senegalensis*) and Yellow-billed Shrikes (*Corvinella corvina*). Communal roosts and groups of more than ten individuals only in non-breeding season.
Breeding. Season Sept–Nov in Senegal and Gambia, Aug–Oct in Mali, Jun in Burkina Faso and Niger, Sept–Oct in Nigeria and Sept–Oct in Sudan. Monogamous; breeds in group, all members of which defend territory and co-operate in rearing of young. Nest a lining of leaf spines placed in tree hole. Clutch 3–4 eggs, plain blue; incubation by female alone in captivity, no information on duration of incubation period; chicks fed by both parents and by helpers (both in captivity and in wild), captive female apparently dominant at nest, taking food brought in by other group-members, which fed chicks directly only in her absence; nestling period c. 21 days.
Movements. Mainly resident. Local movement during dry season.
Status and Conservation. Not globally threatened. Not uncommon to common; common in most parts of range. Widely distributed, and utilizes man-modified habitats.
Bibliography. Bannerman (1948), Bates (1934a), Borrow & Demey (2001), Fry *et al.* (2000), McCarthy (2006), Moynihan (1978), Nikolaus (1987), Schifter (1986), Serle (1943b), Shuel (1938), Wilkinson (1988).

83. Rüppell's Glossy Starling

Lamprotornis purpuroptera

French: Choucador de Rüppell **German**: Schweifglanzstar **Spanish**: Estornino de Rüppell
Other common names: Rüppell's Long-tailed Glossy Starling

Taxonomy. *Lamprotornis purpuroptera* Rüppell, 1845, Shoa district, south-western Ethiopia.
Forms a superspecies with *L. caudatus* and *L. mevesii*. Two subspecies recognized.
Subspecies and Distribution.
L. p. aeneocephalus Heuglin, 1863 – E & SE Sudan, NW Eritrea and W Ethiopia.
L. p. purpuroptera Rüppell, 1845 – S Ethiopia, NE DRCongo, Uganda, Rwanda, Burundi, W & S Kenya, SE Somalia, and NW & NE Tanzania.



Descriptive notes. 35 cm; 78–92 g. Large glossy starling with long, graduated tail. Nominate race has crown, chin and side of head blue-green with bronzy sheen, nape blue with purple sheen, mantle and back blue, rump purple; wing blue-green, dark barring on coverts, tertials and outer webs of primaries; tail purple with distinct bars; throat and breast blue-green; belly, flanks, thighs and undertail-coverts purple, bronzy sheen in centre of belly; some individuals have plumage predominantly purple with bronzy sheen; iris creamy white; bill and legs black. Sexes alike in plumage, but differ in mouth colour: dark in males, pale pinkish in females. Juvenile is matt black, with some gloss on crown, mantle and wings, iris dark brown. Race *aeneocephalus* is much larger than nominate, with longer and more graduated tail, and with mantle, back and upper breast more violet, wings more blue (less greenish). Voice. Song a long warbling, relatively musical series consisting of both sweet notes and harsh ones, with some mimicry, each strophe containing 4–10 elements "pa-wee pweet pweet tcheeeoh"; duetting by partners common, male starting and female following. Often extended periods of song during heat of day. Various call notes reported, e.g. "swi-chew" and "kwerr". Also audible wing sounds during interactions with other birds.
Habitat. Grassland with scattered trees and bushes, in arid areas usually near water; occurs at up to 2000 m. Common in cultivated lands and urban areas in Uganda.
Food and Feeding. Described as almost omnivorous; collects food scraps at camp sites. On Laikipia Plateau, Kenya, ate fruit of *Euclea divinorum*, *Ficus*, *Strychnos henningii* and flowers of *Apodytes dimidiata*; insect food included termites (Isoptera). Forages predominantly on ground, where it hops and runs. In pairs and in small groups.
Breeding. Breeds Oct–Dec in Sudan, Mar–Jul in Ethiopia and Eritrea, Aug–Nov in Rwanda, mainly Mar–May in W Kenya and Uganda, Apr–Jul on Laikipia Plateau, Kenya, and Oct–Nov in E Kenya and Tanzania; at Nakuru, in SW Kenya, no clear breeding season, pairs following own individual cycles (hormonal levels revealed no seasonal pattern in this population); newly fledged young in Jul in Somalia. Monogamous; co-operative breeding in some populations, perhaps dependent on ecological conditions. Nest in tree hole 2·5–25 m above ground, or in old hole of woodpecker (Picidae) in *Hyphaene* palm, cavity lined with cow dung and twigs; in captivity, built nest of leaves, rootlets and mud inside nestbox. Clutch 3 eggs, plain blue to bluish-green, or with rusty spots and blotches; in captivity, incubation period c. 14 days, chicks fed mostly by female, nestling period 25 days; in Kenya both parents reported to incubate, both fed young, and helpers at some nests were older siblings of nestlings.
Movements. Presumed resident in most areas; may also be nomadic. Ringed individual in Ethiopia recovered 9 years later, 37 km from capture site.
Status and Conservation. Not globally threatened. Common within most parts of its range; considered the commonest starling species in Uganda. Occurs within many E African protected areas. Old records of possible breeding in NW Somalia.
Bibliography. Amadon (1956), Ash (1994), Ash & Miskell (1998), Benson (1946b), Carswell *et al.* (2005), David & Gosselin (2002a), Dittami (1987), Dyer (1971), Ezra (1933), Fry *et al.* (2000), Jackson & Sclater (1938), McCarthy (2006), Nikolaus (1987), Njoroge *et al.* (2008), Short & Horne (2005), Smith (1957), van Someren (1916), Wickler (1966), Zimmerman *et al.* (1996).

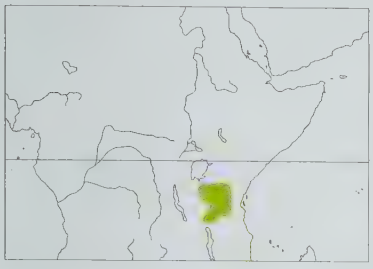
84. Meves's Long-tailed Starling

Lamprotornis mevesii

French: Choucador de Meves **German**: Mevesglanzstar **Spanish**: Estornino de Meves
Other common names: Long-tailed Purple Starling; Angola Glossy Starling (*benguelensis*)

Taxonomy. *Juida Mevesii* Wahlberg, 1856, Okavango River, Botswana.
Forms a superspecies with *L. caudatus* and *L. purpuroptera*. Distinctive race *benguelensis* possibly represents a separate species, differing from others in plumage and habitat; further study required. Three subspecies recognized.
Subspecies and Distribution.
L. m. benguelensis Shelley, 1906 – SW Angola (Benguela S to Namibe).
L. m. violacior Clancey, 1973 – SW Angola (C & S Huila S to Cunene and W Cuando Cubango) and NW Namibia.
L. m. mevesii (Wahlberg, 1856) – extreme SE Angola, extreme NE Namibia, N Botswana, S & E Zambia, S Malawi (R Shire), Zimbabwe (except highlands), W & SW Mozambique and extreme N South Africa (N Limpopo Province).

Descriptive notes. 30 cm; 56–77 g. Fairly large starling with long, strongly graduated tail, central rectrices clearly longest. Nominate race has lores and ear-coverts blackish, often with purple or blue-green gloss on ear-coverts; forehead, crown, nape and mantle blue-green with some purple overtones; back purple, rump bronze, uppertail-coverts purple; wing blue-green, purple sheen on outer webs of primaries, all remiges with faint cross-barring, some wing-coverts with dark blue centre surrounded by blue-green margin; tail blue-violet with heavy dark barring; chin, throat and breast blue-green with slight purple gloss; centre of belly bronze, bordered by purple on flanks and undertail-coverts, thighs blue with purple tone; iris dark brown; bill and legs black. Less contrasting mask, and long, narrow, rounded central rectrices help to separate from *L. australis*. Sexes alike, but female may be duller than male. Juvenile has matt black underparts, some sheen on dorsal plumage. Race *violacior* differs from nominate in having crown to mantle, side of neck, throat and breast strongly violet, violet-blue gloss on wing; *benguelensis* is distinctive, has entire upperparts bronzy green, tail coppery, underparts dark bronzy green, tinged violet on throat and breast. Voice. Song a churring "chwiri-chwirrchwee-chwirr chowee". Harsh "tssac" in alarm.
Habitat. Open woodland with tall trees such as acacias (*Acacia*), mopane (*Colophospermum*) and baobabs (*Adansonia*) with bare ground between, often in seasonally flooded areas; to 1300 m. SW Angolan race *benguelensis* exhibits habitat preference for miombo (*Brachystegia*) woodland, rather than mopane or acacia woodland.
Food and Feeding. Diet chiefly insects, also some fruit. Insects recorded are termites (Isoptera), beetles (Coleoptera), ants (Formicidae), mole-crickets (Gryllotalpidae), and nymphs of psyllids (Psylloidea); fruit such as *Diospyros mespiliformis*, also fruit or flowers of *Acacia albida*. Forages primarily on ground; observed to follow moving African elephants (*Loxodonta africana*), catching insects disturbed by the mammals. In pairs and small flocks; larger flocks of up to 150 individuals outside breeding season, when also large communal roosts in thorn trees noted in Botswana, Zambia and Zimbabwe.
Breeding. Breeds Apr in Angola, Feb in Botswana, Feb–Mar in Zambia, Dec–Mar in Malawi, Nov–Apr in Zimbabwe, and Dec–Mar in South Africa; sometimes double-brooded. Monogamous. Solitary nester; one report of three pairs nesting in single large tree. Nest a simple lining of vegetable matter, placed in hole up to 4 m above ground in baobab, mopane or *Hyphaene* palm, recorded also as utilizing cavity in fence post and ventilation pipe; female may partly excavate cavity in soft wood; nestbox also used. Clutch 3–4 eggs, plain blue; incubation by female alone, period 18 days; chicks fed by both parents, in captivity nestling period 23 days. Nests parasitized by Great Spotted Cuckoo (*Clamator glandarius*) in Zambia, Botswana, Zimbabwe and South Africa; in one case, when nestbox used, cuckoos were attacked and cuckoo egg successfully ejected by starlings.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Locally common in Angola and Namibia; common to locally very common in E parts of range (e.g. river valleys in Zambia). Present in major national parks, although marginal in Kruger National Park, in South Africa, with estimated population of fewer than 300 individuals, minimum of 500 birds in adjacent SW Mozambique, whereas population in CW Mozambique estimated as exceeding 100,000 individuals. Occurs primarily in thinly populated areas.
Bibliography. Amadon (1956), Benson (1953), Berry (1976), Borrett (1973), Brooke (1965a, 1967a, 1971), Colebrook-Robjent & Greenberg (1976), Craig (2000), Craig & Herremans (1997c), Dean (2000b), Dean & Macdonald (1981), Dean *et al.* (1987), Dowsett (1967), Dowsett *et al.* (2008), Fry *et al.* (2000), Gargett (1984), Guy (1976), Herremans-Tonnoeyr *et al.* (1995), Hockey *et al.* (2005), Irwin & Benson (1967), Jubb (1952), Kemp *et al.* (2001), Parker (1999, 2005), Penzhorn & Cassidy (1985), Richard (1975), Thomson (1975), Wilson (1975).



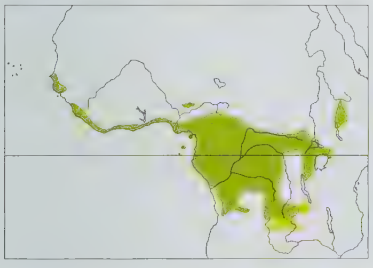
85. Ashy Starling

Lamprotornis unicolor

French: Choucador cendré **German**: Grauglanzstar **Spanish**: Estornino Cenizo

Taxonomy. *Cosmopsarus unicolor* Shelley, 1881, Ugogo, Tanzania.

This species and *L. regius* sometimes placed in a separate genus, *Cosmopsarus*; has alternatively been placed in genus *Spreo*. Monotypic.
Distribution. Interior of Tanzania.



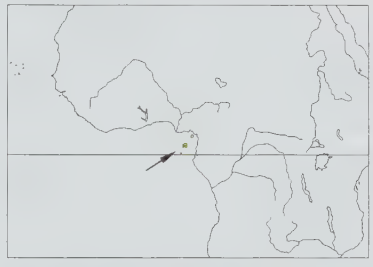
Descriptive notes. 30 cm; 55–66 g. Medium-sized, slender, uniformly coloured starling with very long, narrow tail. Plumage is a uniform ashy grey, with oily-green sheen on remiges and rectrices, some cross-barring visible on rectrices; blackish mask on lores and around eye, often extending over ear-coverts; iris pale cream with maroon-brown to dark sepia-brown inner ring; bill and legs black. Sexes alike. Juvenile is dull ashy brown with pale brown feather tips, iris dark brown, bill horn-coloured. Voice. Song of low conversational notes and harsher elements; often a repeated phrase. Alarm call a harsh "charr"; common contact call 2 squeaky notes, "kuri, kiwera"; also other longer calls.
Habitat. Open dry woodland and wooded grassland, at 1100–1800 m.
Food and Feeding. Diet largely insects; some fruit taken. Insects including termites (Isoptera), grasshoppers (Orthoptera), mantids (Mantodea), dragonflies (Odonata), lacewings (Neuroptera) and caterpillars (Lepidoptera); berries of *Cordia* and *Commiphora* found in some stomach contents; kitchen scraps eaten, including rice and porridge. Forages on ground, in pairs and small flocks.
Breeding. Breeds Feb–Mar. Monogamous; members of one pair bred together for at least 4 successive years. Co-operative breeding regular, helpers being offspring from previous broods (one helped parents in third and fourth years); each of four nests in Tanzania had one or two helpers. Nest in hole 5–16 m above ground in baobab or other tree, or in palm, often old hole of barbet (Capitonidae) or woodpecker (Picidae), into which dry grass carried; captives used nestbox, forming a cup in peat lining, but no other material added. Clutch 3–4 eggs, pale greenish-blue with brown speckles and reddish-brown spots; incubation period in captivity 14 days; chicks fed by both parents and by helpers, in captivity nestling period 26–31 days.
Movements. Presumed resident; some coastal records may represent dry-season movement.
Status and Conservation. Not globally threatened. Common within limited range. Occurs in several national parks.
Bibliography. Baker & Howell (1992), Brown & Britton (1980), Fry *et al.* (2000), Fuggles-Couchman (1939, 1984), Thomas (1960), Wilkinson & McLeod (1991), Zimmerman *et al.* (1996).

86. Splendid Glossy Starling

Lamprotornis splendidus

French: Choucador splendide **German**: Prachtglanzstar **Spanish**: Estornino Espléndido

Taxonomy. *T[urdus] splendidus* Vieillot, 1822, Malimbe, Cabinda, Angola.
Races *bailundensis* intergrades with nominate in N Angola (Malanje). Four subspecies recognized.
Subspecies and Distribution.
L. s. chrysonotis Swainson, 1837 – from Senegal E along coast to S Togo.
L. s. splendidus (Vieillot, 1822) – S Benin, Nigeria, Príncipe I (in Gulf of Guinea) and C & S Cameroon E to S Sudan and W Ethiopia, S to PRCongo, N Angola, C DRCongo, Uganda, W Kenya, Rwanda, Burundi and NW Tanzania.
L. s. lessoni (Pucheran, 1859) – Bioko I (Fernando Póo).
L. s. bailundensis (Neumann, 1920) – N & E Angola, S DRCongo and Zambia.



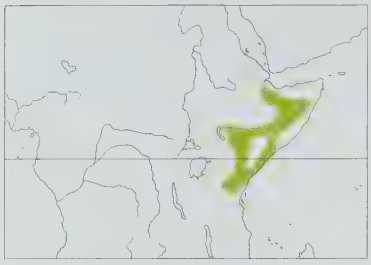
Descriptive notes. 28 cm; 111–155 g. Large glossy starling with brilliant iridescence, medium-length tail. Male nominate race has crown glossy blue-green, sharply demarcated from glossy green nape and mantle; back iridescent blue, tinged with purple, rump glossy blue-green, some barring on tips of uppertail-coverts; wing glossy green, wing-coverts with large subterminal blue spots and blue tips, secondaries and tertials have blue tips and dark purple outer webs, primaries P6–P9 have large notch on inner vane; tail feathers purple at base, broad terminal band of blue-green; small triangular golden-bronze patch between ear-coverts and throat; chin, throat, breast and upper belly purple with bronze sheen, passing into violet on flanks; thighs purple, lower belly and undertail-coverts iridescent blue; iris yellowish-white; bill and legs black. Female resembles male in pattern, but duller, with crown green, not contrasting with nape, no purple gloss and blue wash on back, bronze on underparts restricted to centre of belly, purple below partly replaced by blue. Juvenile initially has gloss only on wing and tail feathers, with belly matt grey, iris brown. Race *lessoni* is like nominate but larger; *chrysonotis* has green crown and blue (rather than purple) throat; *bailundensis* has crown, nape and back uniformly green, and blue (not green) lesser wing-coverts. Voice. Song loud, sounding (to human ear) strongly discordant, containing various gurgling, creaking and plopping sounds, including imitations of other bird species and of primates. Birds often sing in chorus from large trees during hottest period of day, also at roosts. Harsh alarm calls, ringing flight calls also reported. Captives produced accurate mimicry of human voice. Also loud wing noise in flight, has been likened to sound of distant churning of a stern-wheel steamer.
Habitat. Primary and secondary lowland forest, including isolated forest patches and gallery forest; parks and gardens with tall trees; mangroves on offshore islands, and plantations and disturbed habitats. Sea-level to 2000 m; to 2300 in E Africa. On Príncipe I restricted to lowland forest, plantations and farmland.
Food and Feeding. Diet predominantly fruit, also insects; occasionally other animals, including frogs, lizards and snails (Gastropoda). Fruits recorded as eaten include those of *Ficus*, *Pycnanthus*, *Rauwolfia*, *Dacryodes*, *Polyalthia*, *Trichoscypha*, *Coelocaryon*, *Xylopia*, *Beilschmiedia*, *Musanga*; insects such as beetles (Coleoptera), grasshoppers (Orthoptera), termites (Isoptera), ants and wasps (Hymenoptera). Apparently entirely arboreal, foraging mainly in canopy above 30 m, but sometimes descending to lower bushes. In small flocks; joins mixed-species flocks of frugivores when feeding.
Breeding. Breeds Dec–May in much of W Africa; Jan–Mar (in breeding condition also in Jul and Dec) in Gabon; in breeding condition Aug–Sept in Angola; Jan–Aug (peak Feb–Apr) in E Africa, but Nov–Mar in Rwanda; Sept–Nov in Zambia and S DRCongo. Monogamous. Nest a lining of grass, twigs, stems of creepers, or leaf petioles, placed in tree hole at height ranging from 2 m to 37 m; site may be reused in successive years. Clutch 2 eggs, blue-green spotted with red; both in captivity and in wild, female alone incubates eggs while male perches nearby, and both sexes feed nestlings; in captivity, incubation and nestling periods each c. 18 days. Competition for nest-holes with Cinnamon Rollers (*Eurystomus glaucurus*) resulted in destruction of some eggs of present species.
Movements. Primarily resident, with some local movements. Presumed resident on Bioko I, but irregular visitor on Príncipe. Large dry-season roosts in Gabon, from which birds disperse over radius of 15–20 km; similar concentrations with daily dispersal reported from Nigeria and Cameroon, but no clear evidence of seasonal movements, and considered nomadic over a large area. In Ghana and Togo resident in forested zone; local movements evident in Benin. In Uganda mainly resident, with seasonal changes in abundance; in Kenya apparently a breeding migrant, and in Zambia absent during Feb–Jun. Large flocks throughout presence in Zambia suggest that much of visiting population does not breed there; possible that only S race *bailundensis* is migratory, breeding on S margins of range, and then returning to non-breeding areas in Congo Basin.
Status and Conservation. Not globally threatened. Common to not uncommon in W Africa, where locally very common; common in Angola; common to locally very common in Ethiopia; generally uncommon in extreme E parts of range. Has extensive breeding range and is highly mobile; roosts in Gabon reported as holding tens of thousands of individuals. In early years of 20th century was collected on a large scale for plumage, but direct persecution no longer a factor.
Bibliography. Amadon (1956), Anciaux (2002), Basilio (1963), Bates (1909), Benson (1982), Borrow & Demey (2001), Brosset & Érard (1986), Carswell *et al.* (2005), Chapin (1954), Christy & Clarke (1994, 1998, 2006), Dean (2000b), Dowsett *et al.* (2008), Fry *et al.* (2000), Gatter (1997), Marchant (1953), de Naurois (1983, 1994), Nikolaus (1987), Penry (1979), Pettet (1975), Prigogine (1983), Prigogine & Benson (1979), Sawyer (1982).

87. Principe Glossy Starling

Lamprotornis ornatus

French: Choucador de Principé **German**: Prinzenglanzstar **Spanish**: Estornino de Príncipe

Taxonomy. *Sturnus ornatus* Daudin, 1800, Príncipe Island.
Monotypic.
Distribution. Príncipe I, in Gulf of Guinea.



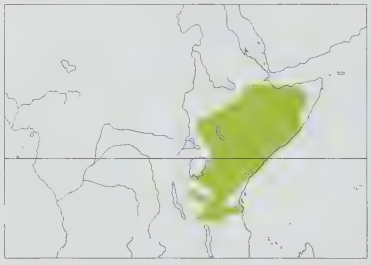
Descriptive notes. 30 cm; 130 g. Large, iridescent starling with medium-length tail. Male has crown, nape and upper mantle glossy bluish-green, back and rump glossy golden-bronze with violet margins of feathers, uppertail-coverts turquoise, tinged with violet; lores blackish, ear-coverts violet, cheek green tipped with turquoise; upperwing with lesser coverts turquoise with violet centres, greater coverts velvety black with violet tips, secondaries and tertials golden-bronze with dark barring, primaries black with turquoise and violet tips and margins, conspicuous notches on inner webs of primaries P6–P9; tail dark bronzy black with some cross-barring, tips of feathers violet and turquoise; chin, throat, breast and belly dark coppery-green, becoming dark glossy green with purplish tinge on flanks and thighs, undertail-coverts deep violet-blue; iris white; bill and legs black. Female resembles male in pattern but less glossy, greener on head and mantle, more blue on rump and tail. Juvenile has some sheen on upperparts, underparts matt grey. Voice. Song of short, disjointed phrases, apparently similar to that of *L. splendidus*, notes also likened to those of orioles (*Oriolus*). Probable alarm call a loud caw; musical "tu-ping" may be contact call. Loud swishing wing noise in flight.
Habitat. Forest, also plantations and disturbed habitats; at low and medium altitudes. When *L. splendius* present, appears generally to retreat to higher forests.
Food and Feeding. Diet apparently fruit, with some animal food. Fruit taken includes bananas, *Ficus*, *Dacryodes* and berries of *Dracaena draco*; animal items spiders (Araneae), small snails (Gastropoda), and caterpillars (Lepidoptera), termites (Isoptera) and other insects. Forages primarily in trees. Hawks termite alates in air. In pairs and in small groups of up to ten individuals; sometimes in flocks with *L. splendius*.
Breeding. Breeding reported in Jan–Feb and nest-building noted in Sept. Nest in tree hole, one 10 m above ground; both sexes seen to carry material. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Príncipe EBA. Common; one of the commonest bird species on the island. Might perhaps be vulnerable to deforestation.
Bibliography. Bannerman (1948), Christy & Clarke (1998, 2006), Feare & Craig (1998), Fry *et al.* (2000), Jones & Tye (1988), de Naurois (1983, 1994), Snow (1950).

88. Golden-breasted Starling

Lamprotornis regius

French: Choucador royal **German**: Königsglanzstar **Spanish**: Estornino Pechidorado
Other common names: Regal Starling

Taxonomy. *Cosmopsarus regius* Reichenow, 1879, Massa, Tana River, Kenya.
This species and *L. unicolor* sometimes placed in a separate genus, *Cosmopsarus*. Proposed race *magnificus* (described from Tsavo, in S Kenya) appears inseparable from birds in rest of species' range. Monotypic.
Distribution. S & E Ethiopia, Somalia, E Kenya and NE Tanzania.
Descriptive notes. 30 cm; 46–63 g. Highly distinctive, colourful starling with very long, narrow, graduated tail. Has crown, nape, chin, throat and cheek glossy greenish-blue, lores and ear-coverts turquoise; mantle and back greenish-blue, glossed with purple, rump turquoise blue; upperwing greenish-blue, small dark terminal spots on wing-coverts (often visible only at close range), primaries P6–P9 strongly indented on inner web; tail bronze with faint transverse barring; breast has purple patch in shape of half-moon, passing into blue towards throat; remainder of breast and flanks, belly, thighs and undertail-coverts golden-yellow, underwing-coverts golden-yellow; iris white; bill and legs black. Sexes alike in plumage, female on average shorter-tailed than male. Juvenile has head, throat and breast matt grey, some greenish gloss on back and rump, violet gloss



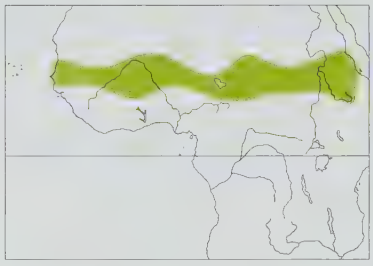
on remiges and rectrices, underparts buffy yellow, iris dark brown, bill and legs dark brown. Voice. Song, often from tree during heat of day, an extended warbling. Alarm call harsh "chairr"; flight call "cheeo cheeo".
Habitat. Dry bush and savanna in arid and semi-arid regions; sea-level to c. 1200 m, generally below 1000 m.
Food and Feeding. Diet consists primarily of insects, also some fruit of *Commiphora* and *Dobera*. Insects include beetles (Coleoptera), ants (Formicidae), caterpillars (Lepidoptera) and termites (Isoptera). In Tsavo, in S Kenya, 76% of 394 food items were insects, 97% of them collected on the ground. Forages mainly on ground; also searches foliage and hawks flying insects. Often in small groups or loosely associated with *L. fischeri*.
Breeding. Season Mar–May in Ethiopia, Apr–Jun in Somalia, Mar–May and Nov–Dec (during both rainy seasons) in Kenya; may be double-brooded. Monogamous; co-operative breeder, up to nine adults attending some nests. Nest in tree hole, either natural hole or disused hole of barbet (Capitonidae) or woodpecker (Picidae), 3–7 m above ground, lined with dry grass, animal hair, feathers, leaves and sometimes shed snakeskins, material brought in by both parents and by helpers; in captivity used nestbox, lined with leaves, moss and, finally, feathers. Clutch 3–4 eggs, pale greenish-blue with fine reddish-brown speckles; incubation by female, fed at nest by male and helpers, in captivity incubation period 14 days; young fed by both parents and by helpers, at Kenyan nests female solicited food from helpers and then fed chicks, in captivity nestling period 19–22 days.
Movements. Presumed resident; some fluctuation in numbers (as in Tsavo region of Kenya) suggests local movements in dry season.
Status and Conservation. Not globally threatened. Common. Inhabits thinly populated regions, and common in national parks within its range.
Bibliography. Bell, K. (1984), Benson (1946b), Boosey (1959), Fry *et al.* (2000), Huels (1981), Lack (1985), Lack & Quicke (1978), McCarthy (2006), Risdon (1990), van Someren (1956), Wavertree (1930).

89. **Superb Starling**

Lamprotornis superbus

French: Choucador superbe **German**: Dreifarben-Glanzstar **Spanish**: Estornino Soberbio

Taxonomy. *Lamprocolius superbus* Rüppell, 1845, Shoa, Ethiopia.
Monotypic.
Distribution. SE Sudan, NE Uganda, S, C & E Ethiopia, Somalia (except NE) and Kenya S to C Tanzania.



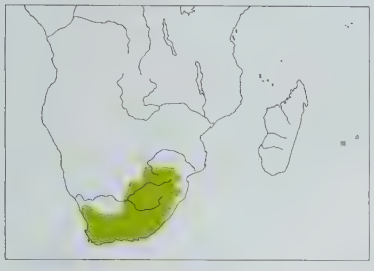
Descriptive notes. 18 cm; 52–77 g. Small, short-tailed starling with distinctive plumage pattern. Crown and ear-coverts are bronzy black, nape, mantle, back and rump glossy blue-green, nape with blue tone; upperwing glossy metallic green, dark velvety black spots on tips of coverts, inner web of primaries P6–P9 indented, outer web of primaries P5–P8 attenuated; tail glossy blue-green; chin, throat and breast glossy blue-green, separated by narrow white band from chestnut-brown belly, flanks and thighs; undertail-coverts and underwing-coverts white; iris creamy white; bill and legs black. Sexes alike. Juvenile is much duller than adult, lacking gloss on wing and tail, although plumage pattern still clearly defined, iris dark brown, bill yellowish (darkening from tip), legs brown. Voice. Song, often given for extended periods from shady trees during hottest hours of day, a long and rambling series of elements, quiet and musical; in captivity both sexes sang, female much less frequently than male. Warning "chirr" call and repeated "whit-chor-chi-vii" in agitation; distinct alarm calls for aerial and terrestrial predators, recognized by vervet monkeys (*Cercopithecus aethiops*) in Amboseli National Park (Kenya); "skrrrri" flight call.
Habitat. Open woodland, including very arid country; also lakeshore woodlands, cultivated areas and gardens, and around human habitation. Found at up to 3000 m; generally avoids humid lowland areas, but present on N Kenyan coast.
Food and Feeding. Diet chiefly insects, such as beetles (Coleoptera), ants (Formicidae), flies (Diptera), termites (Isoptera), grasshoppers (Orthoptera), mantids (Mantodea), caterpillars (Lepidoptera); also berries and small fruits *Carissa edulis*, *Rhus*, *Ficus*, *Apodytes dimidiata*, and nectar from *Agave sisalana*. In Tsavo, in S Kenya, 87% of 597 food items were insects, all taken from ground; 10% of food was fruit, 3% acacia (*Acacia*) flowers. Most food items collected on ground, where it both runs and hops; a bold scavenger around settlements and picnic sites. In small flocks of up to a dozen or so individuals. In Somalia often associated with *L. chalybaeus* and White-headed Buffalo Weavers (*Dinemellia dinemelli*), less often also with *L. shelleyi*; forages with *L. albicapillus* and Stresemann's Bushcrows (*Zavattariornis stresemanni*) in Ethiopia; associates with *L. hildebrandti* in Kenya and with Rufous-tailed Weavers (*Histurgops ruficauda*) and Red-billed Buffalo Weavers (*Bubalornis niger*) in Tanzania. Roosts in nests of *Histurgops ruficauda* and of White-browed Sparrow-weaver (*Plocepasser mahali*). Anting observed in Kenya.
Breeding. Oct–Feb in Ethiopia and Mar–Jun in Somalia; recorded in all months, with peaks Mar–Apr and Nov–Dec; in E Africa, on Laikipia Plateau, Kenya, May–Jul; timing by individual pairs evidently influenced by pre-breeding environmental conditions. Primarily monogamous, but female also solicits extra-pair copulations (apparently more likely to mate with other males within group when fewer helpers available), at times also seeks copulations with non-members of home group (of 247 offspring sampled, 14% were from extra-pair matings; in 25% of 100 nests, at least one young was fathered by a male other than social mate of breeding female). Co-operative breeder, most breeding pairs having helpers, majority of which are male offspring from previous broods; helpers contribute nesting material and feed young, but do not feed female on nest. Nest a large domed structure with side entrance, made from twigs, lined with grass and sometimes feathers, placed 1·5–6 m above ground, and well protected by thorns, in thorn tree; occasionally uses tree hole (14% of nests on Laikipia Plateau), or even hole in cliff, thatch of hut, or base of old vulture (Accipitridae) nest, and sometimes utilizes sparrow (*Passer*) nest under house eaves; often takes over nest of *Dinemellia dinemelli*, sometimes ejecting latter's eggs (weavers will on occasion eject present species' eggs), and will also use nest of *Bubalornis niger* or *Histurgops ruficauda*. Clutch 4 eggs, dark blue; incubation by female alone, period 12–14 days; chicks fed by both parents and by helpers, nestling period 17–25 days; young fed by parents and helpers for 4–7 weeks after leaving nest. Brood parasitism by Great Spotted Cuckoo (*Clamator glandarius*) recorded in Kenya. Breeding success low: over four-year period in Kenya 75% of nests failed, 90% of losses due to predation; in another study, of 64 nests, 22 failed during incubation and 25 during nestling period, and remaining 17 nests produced total of 40 fledglings, of which twelve survived to 6 months.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Widespread and abundant within its range. Common in many national parks and other protected areas.
Bibliography. Archer & Godman (1961), Bartmann (1974), Benson (1946b), Bowen (1931a), Brown, L.H. & Newman (1974), Brown, P. (1972), Carswell *et al.* (2005), Clancey (1987b), Ezra (1924), Fry *et al.* (2000), Hauser (1988), Irvine & Irvine (1974), Irwin (1957), Lack (1985), Lawrence (1975), Lewis & Ogola (1989), McCarthy (2006), Nikolaus (1987), Restall (1968a), Rilling (1972), Rubenstein (2007a, 2007b, 2007c), Short & Horne (2005), van Someren (1956), Trevor & Lack (1976).

90. **Chestnut-bellied Starling**

Lamprotornis pulcher

French: Choucador à ventre roux **German**: Rotbauch-Glanzstar **Spanish**: Estornino Ventrirrufo

Taxonomy. *Turdus pulcher* Statius Müller, 1776, Senegal.
Previously sometimes placed in genus *Spreo*. Has been thought to form a superspecies with *L. hildebrandti* and *L. shelleyi*, but exhibits several morphological differences from those two. Proposed race *rufiventris* (described from N Ethiopia) considered indistinguishable from individuals in rest of species' range. Monotypic.
Distribution. Throughout Sahel region, from S Mauritania, Senegal and Gambia, S Mali and Burkina Faso E to C Sudan, Eritrea and NW Ethiopia.



Descriptive notes. 20 cm; 59–76 g. Small, short-tailed, rather dull starling with rufous below. Crown and ear-coverts are charcoal-grey with faint gloss, lores darker, nape and upperparts glossy bronze-green; upperwing glossy bronze-green, basal two-thirds of primaries dull white (producing pale wing patch in flight), primaries P7–P9 emarginated on inner web, P6–P8 attenuated on outer web; tail glossy bronze-green; chin, throat and breast glossy bronze-green, belly, flanks, thighs and undertail-coverts chestnut-brown; iris yellowish-white; bill and legs black. Sexes alike. Juvenile is duller than adult, gloss restricted to wings and tail, underparts chestnut-brown, iris brown, bill yellowish (darkening from tip), legs brown. Voice. Song consists of soft, liquid notes. Call in flocks "whirri whirri"; alarm and mobbing call "churr-churr".
Habitat. Dry thornbush savanna and steppe, also cultivated areas and villages; occurs in dry scrubby areas during dry-season dispersal.
Food and Feeding. Diet mainly insects, including ants (Formicidae), bugs (Hemiptera), flies (Diptera), beetles (Coleoptera), termites (Isoptera) and grasshoppers (Orthoptera); also fruits of *Salvadora*, *Loranthus*, *Lantana* and *Azadirachta*; dead mouse (Muridae), small chameleon (Chamaeleonidae) and kitchen scraps also recorded. Of 79 individuals examined in Nigeria, more than 90% had eaten ants and termites; insects the main food item of 72% of these birds, with fruit in 19% of stomachs and seeds in 9%. Nestlings fed chiefly with termites and grasshoppers; 88% of 648 items brought to nests in Nigeria were insects. Forages primarily on ground. Generally in small flocks; associates with other starlings, and with White-billed Buffalo Weavers (*Bubalornis albirostris*).
Breeding. Season extended, and often two distinct periods; recorded in all months in Senegal, Apr–Jul in Gambia, Apr–Nov in Mali, Jun–Aug in Burkina Faso and Niger, Feb–Jun and Sept–Nov in Nigeria, May–Jul and Oct–Nov in Chad, Jan–Jun and Sept–Nov in Sudan, and Feb–May in Ethiopia. Monogamous. Highly developed co-operative breeding; groups composed of two or more breeding pairs, with 6–26 non-breeding individuals. Nest, built by both members of breeding pair, a free-standing ball of grass with side entrance, lined with feathers and once a snakeskin, placed up to 12 m (generally 2–3 m) above ground in thorny tree such as desert date (*Balanites aegyptiaca*); in Ethiopia and Eritrea nests of *Bubalornis albirostris* used; in Chad breeds in association with *L. chalybaeus*; captives brought grass and leaves into nestbox, but no eggs laid. Clutch 3–5 eggs, blue, with a ring of brown markings and mauve spots near thick end; incubation by breeding female alone, period 13–18 days; chicks fed by breeding pair and by up to 13 helpers (the more helpers, the more successful the nest), nestling period 18–25 days; young fed by helpers for several weeks after leaving nest. Nests occasionally parasitised by Levaillant's Cuckoo (*Clamator levaillantii*) in Mali and Gambia. Fewer than 50% of fledglings survived beyond 3 months. Annual adult survival rate 80% for males, 90% for breeding females.
Movements. Presumed resident; local movements likely in arid habitat with unpredictable conditions. Ranges widely in non-breeding season. Vagrants recorded in Guinea-Bissau, Guinea and N Ivory Coast.
Status and Conservation. Not globally threatened. Locally common to uncommon; abundant in some areas, e.g. Sudan. Rare in N Ghana and N Togo. Wide range in thinly populated regions.
Bibliography. Bates (1934a), Borrow & Demey (2001), Cheesman & Sclater (1936), Fry *et al.* (1988, 2000), Nikolaus (1987), Schifter (1986), Serle (1943b), Smith (1957), Wilkinson (1978a, 1982a, 1982b, 1983), Wilkinson & Brown (1984).

91. **African Pied Starling**

Lamprotornis bicolor

French: Spréo bicolore **German**: Zweifarb-Glanzstar **Spanish**: Estornino Bicolor
Other common names: Pied Starling

Taxonomy. *Turdus bicolor* J. F. Gmelin, 1789, Cape of Good Hope, South Africa.
Until recently was usually placed in genus *Spreo*. Monotypic.
Distribution. South Africa (except NW, N & E), Lesotho and W Swaziland.
Descriptive notes. 25 cm; 93–113 g. Medium-sized dark starling with pale eye. Crown, nape and upperparts are blackish-brown with some greenish sheen; wing and tail blackish with oily green

gloss; chin, throat, breast and thighs blackish-brown with some sheen, belly and undertail-coverts white; iris white; upper mandible black, lower mandible yellow with black tip, yellow wattle at corner of bill; legs black. Sexes alike. Juvenile has matt black plumage, lacking gloss, iris brown, base of lower mandible yellowish-white, wattle at gape white; iris colour changes over two years, extent of yellow on lower mandible also increases. Voice. Song a rambling combination of musical warbling and harsh notes; male may sing for several minutes while perched near nest. Flight call and flight-intention call a characteristic loud "wreek-wreek"; harsh squawk in alarm.

Habitat. Open areas dominated by grassland, and long associated with agricultural regions and open ground around farm homesteads, occurring also on fields near domestic stock. Occurs in villages and small towns in rural areas (absent from larger urban areas). To 2500 m in mountains, and down to sea-level in W of range.

Food and Feeding. Omnivorous. Animal food includes carrion, such as toads (Amphibia) squashed on roads; also small lizards, ticks (Acarina), solifugids (Solifugida), centipedes (Chilopoda), amphipods (Amphipoda); and many insects, such as termites (Isoptera), ants (Formicidae), beetles (Coleoptera), grasshoppers (Orthoptera), dragonflies (Odonata), butterflies and caterpillars (Lepidoptera). Fruits taken include those of *Ficus*, *Lycium*, *Scutia myrtina*; succulent leaves of *Lycium*, arils of *Acacia cyclops*, nectar from *Agave*, *Aloe arborescens*, *Aloe ferox*, *Erythrina caffra*, *Sideroxylon inerme*. Stomach contents included seeds and other plant material from *Atriplex semibaccata*, *Convolvulus*, *Cotoneaster horizontalis*, *Cussonia paniculata*, *Cyperus esculentus*, *Euclea crispa*, *Ligustrum lucidum*, *Medicago sativa*, *Nicandra physaloides*, *Opuntia*, *Portulaca*, *Protasparagus laricinus*, *Sophora japonica*, *Zea mays*. Forages in trees and bushes, but primarily on ground, where it walks and runs; may turn over dry cowpats in search of insects. Often feeds alongside *Sturnus vulgaris* and *Creatophora cinerea*. Forages also in rocky intertidal zone, and visits gardens and orchards; collects kitchen scraps at houses. In small groups; regularly in association with domestic stock, catching insects disturbed by the mammals, and perching on sheep and cattle, from which it removes ectoparasites. Large communal roosts in reedbeds or trees may hold in excess of 1000 individuals; roost-sites shared with Lesser Kestrels (*Falco naumanni*), which responded to starlings' alarm calls; often flocks and roosts with *Creatophora cinerea*.

Breeding. Aug–Nov in SW (winter-rainfall region); elsewhere Sept–Jan and with second minor peak in Apr–May; some breeding records in all months, and commonly double-brooded. Monogamous; regularly co-operative breeder, with up to five helpers, primarily subadult and unpaired individuals. Allofeeding regular, primarily between members of same breeding unit. Nest consists of pads of grass, roots, wool, muddy bits of sedge, even paper and pieces of rope, occasionally snakeskin, usually in tunnel up to 1·8 m deep excavated by the birds themselves in riverbank, gulley or similar site; in parts of Western Cape exclusively in tunnel excavated by European Bee-eaters (*Merops apiaster*), and in one instance displaced incubating bee-eaters and removed their eggs; also utilizes hole in building, hollow in bale of hay or, rarely, natural tree hole, and once found nesting on a wrecked ship c. 200 m from beach. Clutch 2–6 eggs, usually 4, eggs blue-green, plain or sparsely spotted with red; incubation by female only, period 14–16 days; chicks fed by both parents and by helpers, in captivity only by breeding pair (but allofeeding between group-members observed), nestling period 23–27 days. Brood parasitism by Great Spotted Cuckoo (*Clamator glandarius*) frequent, and parasitism by Greater Honeyguide (*Indicator indicator*) recorded in several areas. Successful defence of nest against predators, including Nile monitor (*Varanus niloticus*), mole snake (*Pseudaspis cana*), Cape cobra (*Naja nivea*) and yellow mongoose (*Cynictis penicillata*); European Bee-eaters benefit from nesting in association with present species through protection from predation, despite competition for nesting burrows.

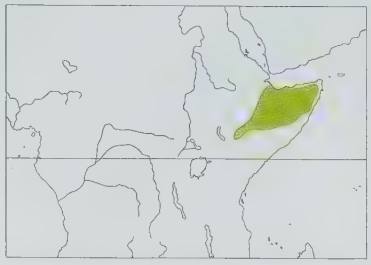
Movements. Mainly sedentary; large nomadic flocks in some regions.

Status and Conservation. Not globally threatened. Common to abundant; uncommon and more local at extremities of range; rare in arid NW and largely absent from E coastal lowlands. Generally widespread, and utilizes man-modified habitats.

Bibliography. Brooke (1995), Craig (1983a, 1983b, 1983c, 1985, 1987, 1988a, 1997d), Dean & Macdonald (1981), Every (1975), Fry *et al.* (2000), Godfrey (1922), Herholdt (1987), Hockey *et al.* (2005), Jacot Guillarmod *et al.* (1979), Jensen & Jensen (1969), Joubert (1945), Jubb (1980b, 1983), Kok & van Ee (1990), McCarthy (2006), van Niekerk (1996), Oatley & Skead (1972), Roberts (1939), Robinson *et al.* (1957), Rudebeck (1955), Skead, C.J. (1995), Skead, D.M. (1966), Sweijd & Craig (1991), Török (1999), Wilkinson *et al.* (1993).

92. White-crowned Starling

Lamprotornis albicapillus



French: Spréo à calotte blanche **Spanish**: Estornino Coroniblanco
German: Weißscheitel-Glanzstar

Taxonomy. *Spreo albicapillus* Blyth, 1855, Somalia.

Until recently was usually placed in genus *Spreo*. Smaller birds from N Kenya and adjacent S Ethiopia described as race *horrensis*; possibly merits recognition, but further study required. Treated as monotypic.

Distribution. S Ethiopia, N Kenya and N & W Somalia.

Descriptive notes. 23–27 cm. Large, pale-eyed starling with distinctive plumage pattern. Has crown white, lores and ear-coverts dull grey, nape and upperparts bronzy green with some gloss; wing glossy bronze-green, outer margins of outer four secondaries and their coverts white (forming white band on folded wing), primaries P6–P9 have indentation on inner web, and P5–P8 attenuated outer web; tail glossy bronze-green; chin, throat, breast and flanks dull grey with some gloss, and white feather shafts producing streaky effect; belly, thighs and undertail-coverts are white; iris yellowish-white; bill and legs black. Sexes alike. Juvenile has grey-white crown, no gloss except on remiges and rectrices, white streaks below are indistinct, iris brown, bill yellow (darkening from tip), legs brown. Voice. Song of upslurred sounds of varied lengths, transcribed as "krrrri-kuri-kuri-koyi". Shrill, rising call and harsh alarm call.

Habitat. Park-like thornveld and acacia (*Acacia*) woodland, also open cattle pastures, and near settlements and cultivated areas; to 1500 m.

Food and Feeding. Diet includes insects, fruit and seeds. Flocks gather at fruiting *Salvadora* trees, and feed on cultivated dates (*Phoenix*) in Somalia; accompanies camels, apparently catching flushed insects. Forages in groups at all times, primarily on ground; often associated with White-headed Buffalo Weaver (*Dinemellia dinemelli*) in Somalia, and with Stresemann's Bushcrow (*Zavattariornis stresemanni*) in Ethiopia.

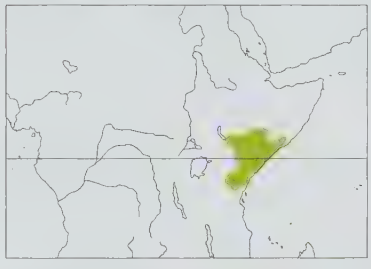
Breeding. Breeds Mar–May in Ethiopia, Mar–Apr in Kenya and Apr–Jun in Somalia. Co-operative breeding suspected, but unconfirmed. Loosely colonial; several nests may be placed in one bush, and usually in scattered colonies. Nest a ball-shaped mass of grass with protruding side entrance, placed c. 1·5 m above ground in thorn bush; in captivity, built a deep, dome-like nest of dry leaves, sticks and moss in a basket. Clutch 4–6 eggs, greenish-blue with purple-red spotting; in captivity, incubation by female alone, period c. 13 days, chicks fed by both parents, nestling period 25 days. Brood parasitism by Great Spotted Cuckoo (*Clamator glandarius*) in Somalia.

Movements. Presumed resident.

Status and Conservation. Not globally threatened. Locally common. Utilizes man-modified habitats. May cause some damage to commercial fruit crops, e.g. cultivated dates in Somalia.

Bibliography. Archer & Godman (1961), Ash & Miskell (1983), Benson (1946b), Boetticher (1936), Clarke (1985), Dellelegn (1993), Ezra (1929), Fry *et al.* (1988, 2000), McCarthy (2006), Petzsch (1951), Turner & Forbes-Watson (1976), Zimmerman *et al.* (1996).

93. Fischer's Starling



Lamprotornis fischeri

French: Spréo de Fischer **German**: Fischerglanzstar **Spanish**: Estornino de Fischer

Taxonomy. *Notauges Fischeri* Reichenow, 1884, plains near Pare Mountains, Moshi District, south of Kilimanjaro, Tanzania.

Until recently was usually placed in genus *Spreo*; has also been placed with *L. unicolor* and *L. regius* in a separate genus, *Cosmopsarus*. Monotypic.

Distribution. SE Ethiopia, S Somalia, E Kenya and NE Tanzania.

Descriptive notes. 18 cm; 51 g. Small starling with white eyes and white on underparts. Cap or whole head paler ash-grey than rest of upperparts and breast, sometimes whitish; rest of upperparts dull ash-grey with some bronze sheen on back and rump; upperwing-coverts grey, flight-feathers and tail dull bronzy green; lores and moustachial stripe black; chin, throat and breast ash-grey, belly, flanks, thighs and undertail-coverts white; iris creamy white; bill and legs black. Sexes alike. Juvenile has upperparts brownish with pale feather edges, iris brown, bill yellowish. Voice. Song a squeaky, metallic phrase, reminiscent of song of Dark-backed Weaver (*Ploceus bicolor*). Call in flock a shrill whistle, also repeated wheezy "cree-wee-creewoo" call.

Habitat. Dry, open thornveld and wooded savanna, to 1900 m.

Food and Feeding. Diet mainly insects, including termites (Isoptera), grasshoppers (Orthoptera), beetles (Coleoptera), and both adult and larval butterflies (Lepidoptera); also berries. In Kenya, insects constituted 99% of 292 food items, all collected from ground. Forages primarily on ground. In pairs and small flocks; may flock with *Creatophora cinerea* or associate loosely with *L. regius*.

Breeding. Apr–May in Ethiopia, Mar–Jun in Somalia, Apr–May and Sept–Nov in Kenya, and Dec in Tanzania. Monogamous; co-operative breeder, up to four adults attending single nest, some individuals fed chicks at more than one nest. Nest a dome of coarse grass with side entrance above small ramp, lined with feathers, placed c. 2·5 m above ground in thorn tree. Clutch 4 eggs, blue with red spots; chicks fed by several adults; no informatin on duration of incubation and nestling periods.

Movements. Presumed resident; seasonal peak in numbers in S Kenya (Tsavo) suggests local movements.

Status and Conservation. Not globally threatened. Locally common. Restricted to a thinly populated region unsuitable for agriculture.

Bibliography. Erlanger (1905), Fry *et al.* (2000), Fuggles-Couchman & Elliott (1946), Lack (1985), Miskell (1977), Njoroge *et al.* (2008), Zimmerman *et al.* (1996).

94. **Lesser Blue-eared Starling**

Lamprotornis chloropterus

French: Choucador de Swainson **German**: Messingglanzstar **Spanish**: Estornino de Swainson **Other common names**: Lesser Blue-eared Glossy Starling, Swainson's Green-tailed Glossy Starling; Miombo Blue-eared/Southern Lesser Blue-eared (Glossy) Starling (*elisabeth*)

Taxonomy. *Lamprotornis chloropterus* Swainson, 1838, Western Africa.
May form a superspecies with *L. acuticaudus*. Races sometimes treated as two distinct species, forming a superspecies. Proposed race *cyanogenys* (described from Sennar, in Sudan) is regarded as a synonym of nominate. Two subspecies recognized.

Subspecies and Distribution.
L. c. chloropterus Swainson, 1838 – Senegal, Gambia, Guinea-Bissau, Guinea, N Sierra Leone, Mali and Ivory Coast E to S Chad, Central African Republic, S Sudan, W Ethiopia, Eritrea, N Uganda and NW Kenya.
L. c. elisabeth (Stresemann, 1924) – SW Uganda, SE Kenya, Tanzania, SE DRCongo, Zambia and Malawi S to extreme NE Namibia (E Caprivi), W Mozambique and Zimbabwe.

Descriptive notes. 18 cm; 63–86 g. Small glossy starling with relatively short tail. Nominate race has forehead, crown, nape and upperparts glossy blue-green, some dark spots near tips of uppertail-coverts; lores and ear-coverts appear black, ear-coverts with blue gloss, forming distinctive patch; wing blue-green, blue gloss on primary coverts, dark velvety spots at tips of median and greater coverts and tertials, bronzy-purple epaulet on bend of wing; tail glossy blue-green; chin, throat, breast, most of belly and undertail-coverts glossy blue-green, flanks, thighs and centre of belly violet-blue; iris orange-yellow; bill and legs black. Sexes alike. Juvenile has greenish sheen above, lacks dark spots on wing-coverts, both epaulet and ear patch are dull and indistinct, has grey-tinged fawn-brown throat and underparts, iris brown to greyish. Race *elisabeth* adult is very like nominate but somewhat less bright green, juvenile is distinctively rufous-brown below. VOICE. Song a simple phrase of 6–12 notes, rendered as e.g. "chip chirrew kwip kreeup kwip krip cheeu". Alarm call a harsh "chair"; flight call clear "wirri-gwirri".

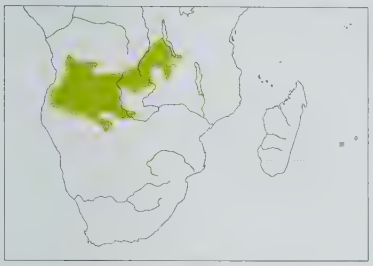
Habitat. Woodland of various types. Mainly in savanna woodland, farmland and bushland in W & N parts of range; S race (*elisabeth*) primarily in miombo (*Brachystegia*) woodland when breeding, later more scattered, entering towns and gardens. Lowlands in most of range, including Ethiopia; in Kenya, above 1000 m in NW (nominate), coastal in SE (*elisabeth*); in S mainly above 800 m, in Malawi generally up to 1700 m.

Food and Feeding. Diet fruit, nectar and insects. Fruit of *Sterculia quinqueloba*, *Ficus natalensis*, and exotics *Azadirachta* and *Michelia champaca*. Nectar of *Bombax* taken. Insects include beetles (Coleoptera), termites (Isoptera), caterpillars (Lepidoptera), and locusts and other grasshoppers (Orthoptera). Forages both in trees and on ground. In pairs when breeding; at other times in small groups and larger flocks, often with *L. chalybaeus* and *L. purpureus*, sometimes with *Cinnyricinclus leucogaster* in W Africa; in Uganda associates with *L. chalcurus*, and in Zambia with *L. acuticaudus*. Roosts of 500–1200 individuals in non-breeding season, and roosting flocks of more than 10,000 reported from Zambia, in reedbeds or trees, sometimes associated with *L. chalybaeus* and *Creatophora cinerea*.

Breeding. Season Feb–Apr in Nigeria (probably also in Ghana); in DRCongo, Mar in N (Uele region) but Sept–Oct in SE (Shaba region); Jun–Jul in Eritrea, and May–Jun in Ethiopia and Kenya; in S (race *elisabeth*) breeds mainly Sept–Oct, with records to Dec in Malawi and possibly to Mar in Zimbabwe. Presumably monogamous; one report suggestive of co-operative breeding. Nest a pile of dry grass and leaves, placed in hole in tree, one nest sited in space between tree trunk and dead bark. Clutch 2–5 eggs, pale blue-green, sparingly spotted with grey and rusty red; young fed by both parents; no information on duration of incubation and nestling periods.

Movements. Presumed resident in most areas, with only very local movements. In Nigeria seasonal shifts linked to rainfall, and in Sudan reported as only a Jul–Oct visitor to Khartoum region; in Zambia, appeared to be a dry-season visitor to most N areas.

Status and Conservation. Not globally threatened. Locally common in many areas within its wide range; true status difficult to assess, as often confused with similar species. Population in C Mozambique estimated at more than 10,000 individuals. Race *elisabeth* occasionally recorded (has bred) in extreme NE South Africa.



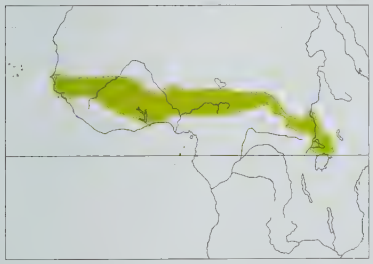
Bibliography. Aspinwall (1978), Belcher (1930), Borrow & Demey (2001), Brooke (1965b), Carswell *et al.* (2005), Cheesman & Sclater (1936), Craig (2000), Dowsett *et al.* (2008), Fry *et al.* (2000), Fuggles-Couchman (1984), Hockey *et al.* (2005), Irwin (1953), Nikolaus (1987), Parker (2005), Serle (1957), Tree (1997).

95. **Sharp-tailed Starling**

Lamprotornis acuticaudus

French: Choucador à queue fine **German**: Keilschwanz-Glanzstar **Spanish**: Estornino Colifino
Other common names: Sharp-tailed Glossy Starling

Taxonomy. *Lamprocolius acuticaudus* Bocage, 1869, Huila, Angola.
May form a superspecies with *L. chloropterus*. Two subspecies recognized.
Subspecies and Distribution.
L. a. acuticaudus (Bocage, 1869) – C Angola (S to SC Huíla), S DRCongo, W & N Zambia and SW Tanzania.
L. a. ecki Clancey, 1980 – S Angola, NE Namibia and extreme NW Botswana.



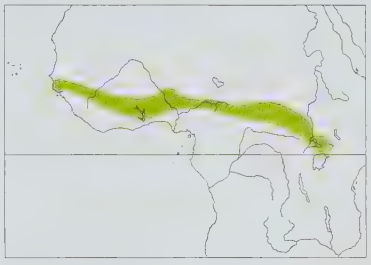
Descriptive notes. 20 cm; 61–76 g. Medium-sized starling with a fairly short, graduated tail. Nominate race has crown, nape and upperparts glossy green; wing glossy green, with bronze-tinged purple patch at bend of wing, dark blue terminal spots on wing-coverts and tertials, primaries P7–P9 have slight indentation on inner web; tail glossy green with faint cross-barring; chin, throat, breast and undertail-coverts glossy green, some blue gloss on belly and flanks; iris red; bill and legs black. Sexes alike in plumage, female possibly with iris orange, rather than red. Juvenile is matt grey with paler feather tips, appearing scaly, some gloss on wings and tail, iris yellow. Race *ecki* is similar to nominate, but has gloss above more greenish-blue, sides of breast and flanks deeper glossy blue, juvenile feather tips whiter (less buffy). Voice. Song is a series of high-pitched warbling and upslurred notes with chuckles and churrs. Contact call is a liquid "puree-o-wit"; twittering calls are made in flocks.
Habitat. Inhabits open woodland, particularly dry miombo (*Brachystegia*) and mopane (*Colophospermum*) country, at altitude range of 900–1700 m.
Food and Feeding. Diet fruit and probably insects; fruit of *Diospyros kirkii* and *Diospyros lycioides* recorded. In pairs and small flocks. Noted as foraging alongside bulbuls (Pycnonotidae) and other starlings in fruiting trees; non-breeding flocks of more than 40 individuals, sometimes with *L. chalybaeus* and *L. chloropterus*.
Breeding. Breeds apparently Aug–Oct in Angola; Oct in Zambia and Nov–Mar in Namibia. Nest a pad of grass, hair and feathers in tree hole. One nest held three young, fed by both adults. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Common in parts of its fairly extensive range. Rare in Botswana, from where very few records.
Bibliography. Boetticher (1931b), Bowen (1931b), Brooke (1968a), Chapin (1954), Clancey (1980b), Craig (2000), Dean (1974a, 2000b), Dean *et al.* (1987), Dowsett *et al.* (2008), Fry *et al.* (2000), Heinrich (1958), Hockey *et al.* (2005), Penry (1986), Underhill & Brown (1997).

96. **Purple Glossy Starling**

Lamprotornis purpureus

French: Choucador pourpré **German**: Purpurglanzstar **Spanish**: Estornino Purpúreo

Taxonomy. *Turdus purpureus* Statius Müller, 1776, Juida = Benin.
Populations from Cameroon E to W Kenya often separated as race *amethystinus* (described from S Sudan), supposedly somewhat bluer above and slightly longer-tailed than those in W of range; further study required. Treated as monotypic.
Distribution. Senegambia, Guinea-Bissau, S Mali and N Guinea E (mainly in savanna belt) to S Chad, N Central African Republic, S Sudan, Uganda and W Kenya.



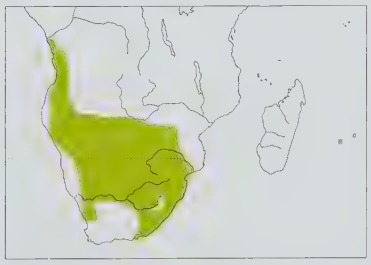
Descriptive notes. 27 cm; 91–140 g. Large glossy starling with short tail and relatively large bill; eye often appears large. Has forehead and crown purple, lores black, nape and hindcrown-band to back of eye blue with some purple gloss; mantle and back blue-green, rump purple; wing blue-green, dark spots on tips of coverts, and blue-and-violet patch forming epaulet; tail purple, two outermost rectrices have blue outer webs; chin, throat and entire underparts to undertail-coverts purple; iris yolk-yellow; bill and legs black. Sexes alike. Juvenile is matt grey, except for gloss on wings and tail (in captivity, first glossy plumage appeared at three months); iris grey, later greenish-yellow. Voice. Song, noted from flocks in trees during heat of day, a sustained chatter. Flight call "twee-twee"; contact call "squee caree"; alarm call "shree".
Habitat. Open savanna woodland N of forested zone, open areas with scattered bushes and trees, also in burnt and cultivated areas; up to 1500 m.
Food and Feeding. Diet fruit, nectar and insects. Fruits of *Ficus* and *Zizyphus*, and of exotic neem (*Azadirachta indica*); nectar of *Bombax costatum* and *Ceiba pentandra*; termites (Isoptera), caterpillars (Lepidoptera) and ants (Formicidae) noted in stomach contents. Forages both in trees and bushes and on ground, often in company with other glossy starlings; hawks insects from trees. Communal roosts in non-breeding season may contain thousands of individuals.
Breeding. Season Apr–Jul in Gambia, Ghana and Nigeria, Mar–May in Sudan, and Feb–Apr in Uganda. Nest in tree hole, sometimes under house eaves or in drainpipe (in Ghana); in captivity, lining of dry grass and leaves in nestbox, and green leaf fragments added even after young hatched. Clutch 2–3 eggs, pale blue, finely speckled with reddish-brown; in captivity, incubation by female only, nestlings fed by both adults; incubation by female only, period 13 days from laying of last egg; nestling period 25 days, nestlings fed by both adults, who squashed insect food before passing it to chicks, and fed young for at least one week after fledging. Captive female mated with male *L. chalybaeus*; two young hatched, but not raised successfully.
Movements. Presumed resident, as present throughout year in most areas; local movements likely, as in e.g. Ivory Coast, where birds move S during dry season. Vagrant in S Mauritania and Liberia.
Status and Conservation. Not globally threatened. Locally common to abundant; perhaps the most abundant glossy starling in parts of W Africa; uncommon in extreme E of range (W Kenya). During early years of 20th century, was one of the species collected on a large scale for the bird-plumage trade in Europe.
Bibliography. Bannerman (1948), Barlow *et al.* (1997), Borrow & Demey (2001), Carswell *et al.* (2005), Fry *et al.* (2000), Grimes (1987), Nikolaus (1987), Pettet (1977), Smith & Schofield (2005), Thomson (1969), Thonnerieux *et al.* (1989), Yusufu & Bello (2004).

97. **Bronze-tailed Glossy Starling**

Lamprotornis chalcurus

French: Choucador à queue violette **German**: Erzglanzstar **Spanish**: Estornino Colibronceado

Taxonomy. *Lamprotornis chalcura* Nordmann, 1835, Senegal.
Populations from N Cameroon E to W Kenya often separated as race *emini* (described from Uganda), supposedly somewhat more violet on rump and slightly longer-tailed than those in W of range; variation, however, appears to be clinal, and further study required. Treated as monotypic.
Distribution. Senegambia, N Guinea-Bissau, S Mali, N Guinea, N Ivory Coast and S Burkina Faso E (mainly in savanna belt) to S Chad, Central African Republic, SW Sudan, Uganda and W Kenya.



Descriptive notes. 21 cm; 63 g. Fairly large, green-looking starling with short tail. Forehead, crown, nape and mantle are iridescent blue-green, lores black, back and rump blue with purple tinge; ear-coverts purple; wing blue-green, coverts and tertial with dark blue tips, bend of wing with blue-and-purple epaulet, inner webs of primaries P6–P9 with indentation; tail purple with bronzy gloss and faint barring, outermost rectrices blue; chin, throat, breast, thighs and undertail-coverts blue-green, belly purple; iris yellow; bill and legs black. Sexes alike. Juvenile is blackish with slight blue tinge above, dull sooty black below, rectrices greenish, iris dark. Voice. Song a combination of nasal, chattering and whistled elements, often in chorus. Contact call "ju-wee-yurr". Loud wing noise in flight.
Habitat. Open bushed and wooded country, also cultivated areas around villages and suburbs, mainly in lowlands; in E of range 500–2000 m, in Kenya above 1000 m and in regions of high rainfall.
Food and Feeding. Stomach contents of specimens contained insects and fruits; second-hand report of scavenging from meat at abattoirs. Forages mostly on ground, less so in trees. In pairs when breeding; at other times in flocks, sometimes quite large ones, and associates with both *L. chalybaeus* and *L. chloropterus*.
Breeding. Breeding reported in Aug in Senegal, May–Jun in Nigeria, Feb–Mar in NE DRCongo and Apr in Kenya. Nest a lining of grass, leaves and feathers in tree hole or stump. Clutch up to 4 eggs, plain pale blue, or finely speckled with orange-brown; incubation apparently by female. No other information.
Movements. Mainly resident. Status in some places unclear; described as a migrant in Sudan, present Sept–Apr; also evidence of seasonal movements in Ghana, and transient flocks in Gambia Oct–Nov.
Status and Conservation. Not globally threatened. Poorly documented, as often not separable in the field from similar congeners (especially *L. chloropterus*). Appears to be locally common to uncommon in much of range; generally uncommon in E (NE DRCongo, Uganda, W Kenya).
Bibliography. Borrow & Demey (2001), Carswell *et al.* (2005), Chapin (1954), Davey (1982), Fry *et al.* (2000), Lewis & Pomeroy (1989), Lowe (1937), Nikolaus (1987), Serle (1943b), Zimmerman *et al.* (1996).

98. **Cape Glossy Starling**

Lamprotornis nitens

French: Choucador à épaulettes rouges **Spanish**: Estornino de El Cabo
German: Rotschulter-Glanzstar
Other common names: Red-shouldered Glossy Starling

Taxonomy. *Turdus nitens* Linnaeus, 1766, Angola.
Birds from Namibia E to Zimbabwe and NE South Africa often separated as race *phoenicopterus* and those from E South Africa as *culminator* on basis of size and colour (larger and greener); geographical variation, however, appears clinal, with intergradation between adjoining populations throughout species' range. Treated as monotypic.

Distribution. From around mouth of R Congo S through W & S Angola to SW Zambia and Zimbabwe, S to Namibia, Botswana, South Africa (except S & SW Cape region and dry W interior), W lowlands of Lesotho, Swaziland and S Mozambique.
Descriptive notes. 25 cm; 75–105 g. Fairly large, short-tailed glossy starling with rather uniform appearance. Head is glossy blue, blacker on ear-coverts; upperparts blue-green with strong iridescence; wing blue-green, dark blue spots at tips of some median and greater coverts, distinct bronzy-purple epaulet, primaries P6–P9 strongly indented on inner webs; tail glossy blue-green; throat and upper breast have blue iridescence, lower breast, belly and undertail-coverts with greener gloss; iris bright orange-yellow; bill and legs black. Sexes alike. Juvenile is

On following page: 99. Emerald Starling (*Lamprotornis iris*); 100. Greater Blue-eared Starling (*Lamprotornis chalybaeus*);

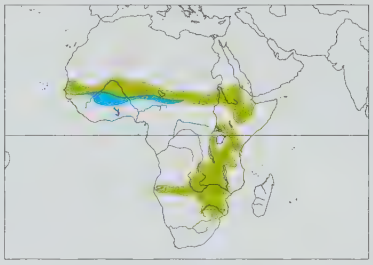
dull-plumaged, with matt black underparts, iris initially grey; at three months iris dull yellow, acquiring adult colour after six months. Voice. Song a sustained warbling with varied notes, and may include imitation of other bird species; sings throughout year, in chorus at roost-sites in morning and evening, also often at midday when perched in shady tree; male sings near nest-site while female incubating. Alarm call a harsh "kaarr"; flight call a rolling "turrrreeu". Loud swishing wing noise in flight.
Habitat. Savanna woodland and riverine vegetation; in arid areas restricted to taller trees along watercourses. Also forest edge, plantations, parks and gardens. From sea-level to 1800 m.
Food and Feeding. Omnivorous; diet chiefly fruit and insects, but also other animal food including mammalian carrion, ticks (Acarina) and millipedes (Diplopoda); takes bread and bone meal at birdtables. Fruit such as *Ficus*, *Lycium*, *Rhus*, *Olea*, *Scutia myrtina*, *Azima tetracantha*, *Diospyros pubescens*, *Atriplex bacifera*; nectar of *Erythrina caffra*, *Boscia albitrunca*, *Protea subvestita*, *Grevillea*, and numerous species of *Aloe* also taken. Insects recorded as eaten are wasps and ants (Hymenoptera), including the ant *Plagiolepis custodiens* (filled with honeydew), grasshoppers (Orthoptera), termites (Isoptera), beetles (Coleoptera), caterpillars (Lepidoptera) and flies (Diptera). Forages both in trees and bushes and on ground. Often feeds in association with grazing ungulates such as cattle, blue wildebeest (*Connochaetes taurinus*), impala (*Aepyceros melampus*) and white rhinoceros (*Ceratotherium simum*); may perch on the animals to hawk flies, and gleans ectoparasites from cattle, sable antelope (*Hippotragus niger*) and gemsbok (*Oryx gazella*). Usually in groups of up to c. 20 individuals, sometimes in much larger flocks; occasionally joins mixed-species flocks of insectivorous birds feeding in woodland in South Africa. Roosts in small groups in trees.
Breeding. Breeds Sept–Feb/Mar in S Africa, and probably Feb–Mar in Angola. Monogamous. Co-operative breeder, most helpers probably offspring of breeding pair; some remain as helpers for up to three years. Nest built by both sexes, material including horse and cow dung, dry grass, feathers, and shed snakeskins, helpers may bring feathers to female during incubation, placed usually in tree hole, including old hole of woodpecker (Picidae) or barbet (Capitonidae), rarely hole in riverbank; man-made structure such as fence post, hollow metal post or pipe sometimes used, or nest sited under roof or even in wooden postbox in daily use; twigs and other material may be used to fill up cavity until nest closer to entrance; pairs using nestboxes in Namibia selected those more than 2 m above ground. Clutch 3 eggs, pale greenish-blue, speckled with light red; incubation by female alone, period 12–14 days; young fed by both parents, and by at least three helpers, nestling period c. 20 days. Nests parasitized by Great Spotted Cuckoo (*Clamator glandarius*) in Namibia and probably elsewhere; one record of nest containing egg of Greater Honeyguide (*Indicator indicator*).
Movements. Presumed resident; in one garden, ringed individuals remained on same territory for four years.
Status and Conservation. Not globally threatened. Widespread and common in much of range. Population in Kruger National Park, in NE South Africa, estimated at more than 32,000 individuals, in Kgalagadi Transfrontier Park (SW Botswana–South Africa border) at 16,000 or more, and in S Mozambique at more than 40,000 birds. Recorded in S PRCongo and possibly in Gabon. No breeding records from Zambia. Common in many protected areas.
Bibliography. Amadon (1956), Barry (1998), Borrow & Demey (2001), Cole (1963), Craig (1983a, 1983c, 1997f, 2000), Dean (2000b), Donnelly (1966, 1967), Dowsett *et al.* (2008), Fry *et al.* (2000), Godfrey (1922), Hockey *et al.* (2005), Hoesch & Niethammer (1940), Kannemeyer (1951), Kemp *et al.* (2001), Macdonald (1957), Newman (1971), Oatley & Skead (1972), Parker (1999), Penzhorn (1982), Plowes (1944), Riekert & Clinning (1985), Skead (1995), Taylor (1951), Thomson & Ferguson (2007), Vernon (1973).

99. Emerald Starling

Lamprotornis iris

French: Choucador iris **German**: Schillerglanzstar **Spanish**: Estornino Esmeralda
Other common names: Emerald Glossy Starling, Iris Glossy Starling

Taxonomy. *Coccycolius iris* Oustalet, 1879, Los Islands, coast of Guinea, probably error = interior Guinea.
Sometimes placed in a monotypic genus *Coccycolius*. Monotypic.
Distribution. Guinea, N Sierra Leone and C Ivory Coast.



Descriptive notes. 21 cm. Small, distinctive, glossy green starling with medium-length tail. Has curved patch of purple from behind eye, extending over ear-coverts and down towards side of throat; rest of head, upperparts, including wing and tail, and chin, throat, upper breast and undertail-coverts brilliant emerald-green; belly glossed purple, thighs grey without iridescence; iris dark brown; bill and legs black. Sexes alike. Juvenile is duller than adult, with dorsal plumage glossy olive-green, underparts matt grey-brown. Voice. Wheezy and squeaky calls; captive individual gave high-pitched "pee-pee-pee" in alarm, harsher version when mobbing ground predators.
Habitat. Savanna woodland.
Food and Feeding. Diet fruit and insects. Fruit of *Ficus* and *Harungana madagascariensis*; insects such as ants (Formicidae) and caterpillars (Lepidoptera). Forages on ground, as well as in tops of trees. In small groups.
Breeding. Breeding in Mar in Sierra Leone. May be a co-operative breeder, as captive groups seen to have helpers, latter including adults and immatures of both sexes. Nest in tree hole; in captivity, used tree hole or nestbox, lining this with both dry and green material, green leaves taken from living plants. Clutch 3–4 eggs, pale blue with red-brown blotching; in captivity, incubation by female alone, period 14 days, chicks fed by both parents and in some cases by helpers, nestling period 21 days.
Movements. Presumed resident; some local movements, possibly seasonal. Vagrant recorded in SW Mali.
Status and Conservation. Data-deficient. Very poorly known. Reported as locally common within its limited range. Can be bred successfully in captivity.
Bibliography. Anon. (2008b), Bannerman (1932, 1948), Borrow & Demey (2001), Bruch (1983), Butchart & Stattersfield (2004), Feare & Craig (1998), Fry *et al.* (2000), Pyper (1994), Robiller & Gerstner (1985), Shelton (1982), Stattersfield & Capper (2000), Steinbacher (1980), Wilkinson (1996, 1997).

100. Greater Blue-eared Starling

Lamprotornis chalybaeus

French: Choucador à oreillons bleus **Spanish**: Estornino Orejiazul
German: Grünschwanz-Glanzstar
Other common names: (Greater) Blue-eared/Green Glossy Starling

Taxonomy. *Lamprotornis chalybaeus* Hemprich and Ehrenberg, 1828, Ambukol, Dongla district, Sudan. Race *nordmanni* sometimes treated as a synonym of *sycobius*. Proposed race *hartlaubi* (described from Senegal), formerly used for N populations (E to Sudan), is regarded as synonymous with nominate. Four subspecies recognized.
Subspecies and Distribution.
L. c. chalybaeus Hemprich & Ehrenberg, 1828 – S Mauritania, Senegambia, S Mali, Burkina Faso, S Niger and N Nigeria E to C Sudan; dry-season visitor to N Ivory Coast, Togo and Benin.
L. c. cyaniventris Blyth, 1855 – Eritrea, Ethiopia, NW Somalia, N Uganda, E DRCongo and N Kenya.
L. c. sycobius (Hartlaub, 1859) – SW Uganda, S Kenya, Rwanda, Burundi, Tanzania, SE DRCongo, N & E Zambia, Malawi and W Mozambique.
L. c. nordmanni (E. J. O. Hartert & Neumann, 1914) – S Angola and N Namibia E to N & E Botswana, S Zambia, Zimbabwe, NE South Africa and S Mozambique.

Descriptive notes. 21–24 cm; 79–106 g. Fairly large starling with proportionately short tail. Nominate race has forehead, crown, nape and upperparts blue-green, blue sheen on uppertail-coverts, which also have faint dark spots at tip; lores blackish, ear-coverts glossy blue, forming distinctive patch; wing blue-green, bronzy epaulet on bend of wing, dark spots on tips of greater and median coverts and on tertials, prominent indentation on inner web of primaries P6–P9; tail more blue than rest of dorsal plumage; chin, throat, breast and undertail-coverts glossy blue-green, flanks, belly and thighs blue with violet sheen; iris colour ranges from white and yellow to orange or red (some regional patterns, also individual variation); bill and legs black. Sexes alike. Juvenile much duller, with underlying brown coloration, more gloss on dorsal surface, iris brown to reddish-brown; iris fully yellow by five months. Race *cyaniventris* is larger than nominate, bend of wing violet (not blue); *sycobius* is smaller, with brighter green head and neck; *nordmanni* is like previous, but has patch at bend of wing coppery (not violet). Voice. Song, often in chorus from trees, a rambling jumble of notes with whining tone. Flight call a shrill "kwee-kwee"; characteristic contact call a nasal "skweer"; alarm a harsh "shwarr". Loud wing noise in flight.
Habitat. Inhabits dry savanna woodland, in W Africa extending into desert zone. In E & S parts of range found in regions with higher rainfall, including richer woodland and cultivated areas, also gardens, largely above 500 m; above 2000 m on Ethiopian plateau, but also on coastal belt of Kenya.
Food and Feeding. Diet primarily fruit and insects. Fruit of *Ficus*, *Salvadora persica*, *Trichilia emetica*, *Carissa edulis*, *Euclea divinorum*, *Rhus*, *Olea europaea*, *Aptodytes dimidiata*, *Strychnos henningsii*, *Boscia senegalensis*, *Guibourtia coleosperma* and *Syzygium*; nectar taken from *Agave sisalana*; also ripe cereal grain taken. Insects recorded as eaten are locusts and other grasshoppers (Orthoptera), beetles (Coleoptera), termites (Isoptera), ants (Formicidae). Observed when anting with *Anoplolepis custodiens* in South Africa. Takes food discarded by people in national parks, and meat from carcases. Captive individual killed and ate frogs, lizards and baby mice (Muridae). Most food apparently collected on ground, where it hops, rather than walking or running; forages for fruit and nectar in trees, and hawks flying insects. Associates with ungulates; perches on backs of sheep, African buffalo (*Syncerus caffer*), blue wildebeest (*Connochaetes taurinus*) and Burchell's zebra (*Equus burchellii*). Generally in pairs and small flocks; sometimes up to 300 birds at fruiting trees. Large roosts (holding more than 400 individuals) formed in reedbeds, bushes or thorn trees after breeding.
Breeding. Season mainly Jun–Aug in W Africa; Apr–Jun in Sudan, and May–Sept in Ethiopia, Eritrea and Somalia; Mar–Jun in Uganda and Kenya, but some records in all months in C & E Kenya (evidence of differences in seasonality in adjoining habitats); Oct–Jan in Tanzania, Rwanda and Malawi, and Sept–Dec (mainly Oct–Nov) in Zambia; primarily Oct–Nov in Zimbabwe and South Africa, but some records also Aug–Jan. Monogamous; possible courtship feeding noted in Kenya. Nest in natural hole or old hole of barbet (Capitonidae) or woodpecker (Picidae) 0·5–16 m above ground in tree; in Eritrea reported as using tunnel in vertical bank, and in Mali old nests of White-billed Buffalo Weaver (*Bubalornis albirostris*), Abdim's Stork (*Ciconia abdimii*) and Sacred Ibis (*Threskiornis aethiopicus*) used; one record of nesting in hollow fence post; hole unlined, or lined with grass, leaves, bits of plastic and feathers. Vigorous competition for nest-sites with other hole-nesting species such as rollers (Coraciidae), parrots (Psittacidae) and sympatric sturnids. Clutch 3–5 eggs, clear blue, or blue with fine rusty spots; incubation by female alone, period 13–14 days; chicks fed by both male and female, in captivity mostly by female and nestling period 23 days. Nests parasitized by Great Spotted Cuckoo (*Clamator glandarius*) in S Africa, and reports from S & E Africa of parasitism by Greater Honeyguide (*Indicator indicator*). Some nestling mortality due to mysiasis caused by larvae of the muscid fly *Passeromyia heterochaeta*. Captive male mated with female *L. purpureus*; two hybrid young not raised successfully.
Movements. Presumed resident in most areas. At Nakuru, in Kenya, marked exodus and few birds present Nov–Jan, and wandering flocks of non-breeders noted elsewhere; on Laikipia Plateau largely a breeding visitor Apr–Sept. In W Africa, apparent movement S in dry season.
Status and Conservation. Not globally threatened. Common to locally not uncommon; widespread. Population in Kruger National Park, in South Africa, estimated at more than 32,000 individuals; in S Mozambique more than 100,000 birds, but less common in C Mozambique, where numbers estimated at minimum of 10,000 individuals. Present in many protected areas. In dry season, may cause damage to cereal crops in L Chad basin.
Bibliography. Genus *SAROGLOSSA* Hodgson, 1844

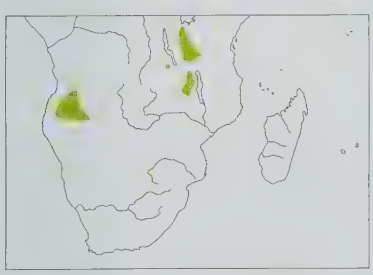
101. **Spot-winged Starling**

Saroglossa spiloptera

French: Choucador à ailes tachetées **German**: Marmorstar **Spanish**: Estornino Alipinto

Taxonomy. *Lamprotornis spilopterus* Vigors, 1831, Simla–Almora district, Himachal Pradesh, India. Monotypic.
Distribution. Breeds in Himalayan foothills in N India (Himachal Pradesh S to N Uttar Pradesh) and Nepal; non-breeding range in Assam, NE & C Bangladesh, Myanmar and W Thailand.

Descriptive notes. 19 cm; 47·5 g. Small, mostly brownish starling with pale eyes. Male has feathers of crown to mantle and back grey with dark borders, rump red-brown; wing blackish with olive sheen, white patch near base of each primary; tail dark rufous-brown; side of head grey, chin and throat dark red-brown; underparts variably chestnut-brown, often pale on chest, pale feather edges in centre of belly, thighs grey; iris white to pale yellow; bill black, brown base; legs dark brown. Female has crown, nape and upperparts grey-brown with pale spot-like areas on feathers, wings and tail dark brown, chin, throat and chest pale brown with dark central streaks, flanks, belly and undertail-coverts dull white. Juvenile resembles female but with more streaking below, brown wash on flanks, brown tips on wing-coverts, iris dark brown to grey. Voice. Song a mix of dry, harsh discordant notes and some more musical warbling. Call from flocks a noisy chattering; aggressive "chek-chek-chek" and chirruping "chik-chik" as contact call by perched individuals.
Habitat. Open forest, clearings and forest edge in hilly country at 700–1000 m, locally to 2000 m. Also in trees in open areas and cultivated areas in lowlands in non-breeding range.
Food and Feeding. Omnivorous. Diet includes fruit, insects and nectar. Berries and figs (*Ficus*) eaten, and nectar taken readily from *Bombax*, *Erythrina* and *Grevillea* trees; insect food noted as red tree ants (Formicidae) and winged termites (Isoptera). Forages mainly in canopy. Gregarious, often in flocks; also associates with *Sturnia malabarica* and *Acridotheres fuscus*.
Breeding. Season Apr–Jun. Monogamous. Nest in natural tree hole or barbet (Capitonidae) hole 6–10 m above ground, cavity lined with green leaves and other material. Clutch 3–4 eggs, pale grey or bluish-green with reddish-brown speckles and blotches; in captivity, both parents fed young and both removed faecal sacs. No other information.
Movements. Migratory. Migrates E in Jun–Jul to non-breeding grounds in NE India (Assam, Meghalaya, Nagaland, Manipur), NE & C Bangladesh, Myanmar and NW & W Thailand; recorded in Myanmar Dec–Feb; return passage W in Mar–Apr. Passage migrant in Sikkim.
Status and Conservation. Not globally threatened. Scarce in breeding areas. Rare to scarce non-breeding visitor in Myanmar and Thailand; possibly no longer occurs in Bangladesh. Seldom kept in captivity.
Bibliography. Ali & Ripley (1972), Collar *et al.* (1994), Fleming & Traylor (1968), Grimmett *et al.* (1998), Inskipp & Inskipp (1991), Lekagul & Round (1991), Marien (1951), Rasmussen & Anderton (2005b), Robson (2000), Scamell (1969), Smythies (1986), Whistler (1923).



Genus *NEOCICHLA* Sharpe, 1876

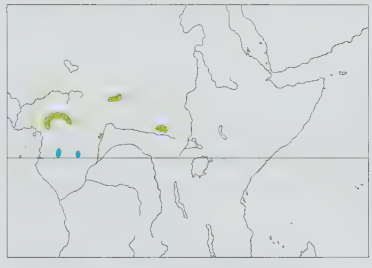
102. **White-winged Babbling Starling**

Neocichla gutturalis

French: Choucador à gorge noire **German**: Weißflügelstar **Spanish**: Estornino Gorjinegro
Other common names: Babbling Starling, White-winged Starling

Taxonomy. *Crateropus gutturalis* Bocage, 1871, Huíla, Angola.
Two subspecies recognized.
Subspecies and Distribution.
N. g. gutturalis (Bocage, 1871) – SC Angola.
N. g. angusta Friedmann, 1930 – WC Tanzania, NW & E Zambia and NW Malawi.

Descriptive notes. 17 cm; 64–72 g. Small starling with distinctive plumage pattern. Nominate race has head, including chin and throat, grey, darker on lores; mantle and back brown with buff feather edges, rump grey-brown; wing brown, some gloss on primaries, white outer edges of secondaries forming prominent band on folded wing (clear wing patch in flight); tail dark brown with some gloss, white tips on outer two pairs of rectrices; small black wedge-shaped mark in centre of breast; rest of underparts buff, paling to white in centre of belly; iris yellow; bill black; legs yellow-brown. Sexes alike. Juvenile has crown and mantle dark brown, throat and underparts with dark brown teardrop markings on pale background, iris grey, bill yellowish with dark tip, legs pale brown. Race *angusta* differs from nominate primarily in having narrower white edges on outer rectrices, paler upperparts. Voice. Song of protracted plaintive sequences of notes interspersed with upslurred squealing sounds; calls described as shrill and like those of a parrot (Psittacidae), or reminiscent of babblers (Timaliidae); scolding alarm call.
Habitat. Open miombo (*Brachystegia*) woodland with little undergrowth, and mixed miombo–mopane (*Brachystegia–Colophospermum*) woodland; to c. 1500 m.
Food and Feeding. Diet includes weevils (Curculionidae) and other Coleoptera, termites (Isoptera); also berries, and observed to probe protea (*Protea*) flowers. Forages primarily on ground. In pairs or in groups of fewer than ten individuals, but flocks of more than 40 birds reported in non-breeding season; may join mixed-species foraging flocks.
Breeding. Breeds Aug–Sept/Oct in Angola, Oct–Nov in Zambia and Nov in Malawi. Presumed monogamous; co-operative breeding suspected, but not confirmed. Nest a lining of lichen, moss and grass, or hair and dry leaves, placed in hole up to 8 m above ground in tree. Clutch 2–3 eggs reported; two adults feeding at one nest. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Poorly known, with apparently relict distribution; isolated population near Nsoma, in NW Zambia. Common in Angola and in parts of E range; everywhere very localized in occurrence. Present in some protected areas.
Bibliography. Benson & Irwin (1966), Chapin (1948), Dean (2000b), Dean & Vernon (1988), Dowsett *et al.* (2008), Dowsett-Lemaire & Dowsett (2006), Friedmann (1930), Fry *et al.* (2000).



Genus *GRAFISIA* Bates, 1926

103. **White-collared Starling**

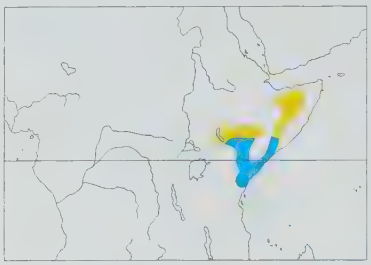
Grafisia torquata

French: Choucador à cou blanc **German**: Ringstar **Spanish**: Estornino Acollarado

Taxonomy. *Spreo torquatus* Reichenow, 1909, Banyo, western Cameroon.
Monotypic.
Distribution. Locally in C Cameroon (Adamawa Plateau and Bamenda Highlands), N Central African Republic, N PRCongo and N DRCongo; non-breeding in Gabon.

Descriptive notes. 21 cm; 61–67 g. Medium-sized, dark starling. Male is uniformly glossy blue-black, except for white patch on upper breast (ending sharply in line with wing); iris orange-yellow with deep orange outer ring; bill and legs black. Female is charcoal-grey without gloss, but feathers from crown to rump tipped blue-black, wing and tail dull black; bare parts as male. Juvenile is like female in pattern, but brownish-grey underparts, iris dark brown. Voice. Song, apparently from both sexes, and perhaps from groups perched in trees, said to be reminiscent of song of *Lamprotornis* species. Call of 3 short whistled notes, and chirruping described.
Habitat. Open woodland and savanna; recorded also in montane grassland to 1200 m in Cameroon.
Food and Feeding. Diet probably mainly fruit; insects also reported in stomach contents. Fruits of *Ficus*, *Musanga*, *Macaranga assas* and *Xylopia aethiopica*. Forages in trees with frugivores, including *Lamprotornis splendidus*; does not descend to ground. Hawks insects from treetops or above canopy. In pairs and small flocks, and once a larger flock of more than 100 individuals in Congo Basin.
Breeding. In breeding condition and possible nest-building in Cameroon in Feb–Mar. No other information.
Movements. Possible seasonal movements; non-breeding visitor in Gabon and parts of PRCongo.
Status and Conservation. Not globally threatened. Very poorly known, and status unclear. Apparently uncommon to locally common within fragmented range.
Bibliography. Bannerman (1948), Blancou (1974), Borrow & Demey (2001), Brosset & Érard (1986), Chapin (1954), Dowsett & Dowsett-Lemaire (1998), Dowsett-Lemaire (1996), Fry *et al.* (2000), Serle (1965).

Genus *SPECULIPASTOR* Reichenow, 1879



104. **Magpie Starling**

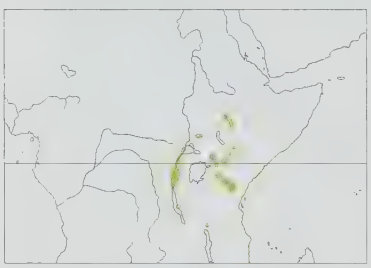
Speculipastor bicolor

French: Choucador pie **German**: Spiegelstar **Spanish**: Estornino Urraca

Taxonomy. *Speculipastor bicolor* Reichenow, 1879, Kipini, Kenya.
Monotypic.
Distribution. Breeds N Kenya, S & E Ethiopia and Somalia; non-breeding E Kenya and S Somalia.
Descriptive notes. 19 cm; 66–69 g. Small starling with white abdomen. Male has head and upperparts, chin, throat and upper breast glossy blue-black, remainder of breast region, belly, flanks, thighs and undertail-coverts white; wing blue-black, white bases of primaries visible as a white bar on folded wing (prominent white band in flight); tail blue-black; iris red; bill and legs black. Female resembles male in plumage pattern but duller, head, throat and upper breast grey, with blue-black feathers restricted to narrow band between bib and the white of lower breast and belly. Juvenile lacks blue-

On following pages: 105. Sharpe's Starling (*Pholia sharpii*); 106. Abbott's Starling (*Pholia femoralis*); 107. Narrow-tailed Starling (*Poeoptera lugubris*); 108. Kenrick's Starling (*Poeoptera kenricki*); 109. Stuhlmann's Starling (*Poeoptera stuhlmanni*); 110. Black-bellied Glossy Starling (*Notopholia corrusca*); 111. Copper-tailed Glossy Starling (*Hylopsar cupreocauda*); 112. Purple-headed Glossy Starling (*Hylopsar purpureiceps*).

black in plumage, has upperparts, chin, throat and breast grey, white areas as in adult, wings and tail grey-brown, iris dark brown, bill and legs brown. Voice. Song a soft babbling with harsher notes; captive male sang for extended periods. Flight call a shrill whistle; alarm a harsh "ti-chuk chuk-chuk".
Habitat. Open bushy and wooded country in arid to semi-arid regions, mainly below 1200 m.
Food and Feeding. Recorded items include fruit of *Ficus*, *Rhus*, *Strychnos henningsii* and *Solanum*; insects such as caterpillars (Lepidoptera). Forages on ground and in trees. Generally flocks of no more than 30 individuals but more than 100 feeding in fruiting trees on occasion.
Breeding. Season May–Jun in Kenya, possibly Feb–Apr in Ethiopia, and Apr–Jun in Somalia; perhaps breeds opportunistically in response to rainfall. Monogamous; evidence of occasional co-operative breeding. Solitary or in small colonies. Nest in hole in side of termite (Isoptera) mound when solitary, also in hole in bank when in colony, breeding chamber 10–20 cm from surface and lined with grass and green leaves; captive pair used nestbox, sparsely lined with grass. Clutch 2–6 eggs, bluish-green, lightly spotted all over with russet brown; in captivity, incubation by female, period c. 18 days, nestlings fed by both adults for 21 days.
Movements. Generally regarded as nomadic; in some areas movements appear to represent regular migration, with clearly defined breeding and non-breeding regions. N Somalia and S Ethiopia may be breeding areas only, whereas Kenya S of equator is wintering area (Aug–Oct). Vagrants recorded in NE Uganda, SE Sudan and N Tanzania.
Status and Conservation. Not globally threatened. Locally common. Occurs in arid regions unsuited to permanent human settlement.
Bibliography. Archer & Godman (1961), Ash & Miskell (1998), Benson (1946b), Carswell *et al.* (2005), Fry *et al.* (2000), Haas & Nickel (1982), Nikolaus (1987), Partridge (1964), Short & Horne (2005), van Someren (1922), Zimmerman *et al.* (1996).



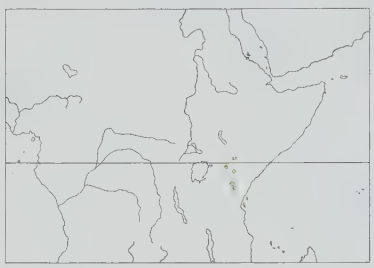
Genus *PHOLIA* Reichenow, 1900

105. **Sharpe's Starling**

Pholia sharpii

French: Choucador de Sharpe **German**: Rostbauchstar **Spanish**: Estornino de Sharpe

Taxonomy. *Pholidauges sharpii* F. J. Jackson, 1898, Eldama Ravine, Kenya.
Genus often subsumed into *Cinnyricinclus*. Has been suggested that this species and *P. femoralis* form a superspecies. Monotypic.
Distribution. SE Sudan, SW Ethiopia, extreme E DRCongo, SW Uganda, W parts of Rwanda and Burundi, Mt Elgon (E Uganda–W Kenya border), C & S Kenya, and N, W & SW Tanzania.



Descriptive notes. 18 cm; 40–56 g. Small starling with distinctive plumage. Has crown, side of head, nape and entire upperside, including wing and tail, glossy blue-black; chin, throat and breast cream-coloured, tinged with buff, also glossy blue-black patch on each side of breast at bend of wing (may suggest partial breastband); belly, flanks, thighs and undertail-coverts buff; iris yellow; bill and legs black. Sexes alike. Juvenile has matt grey upperparts with some sheen on wings and tail, cream-coloured below with dark arrowhead-shaped feather tips, buff wash on thighs and undertail coverts, iris dark brown, pale yellow bill base. Voice. Song, by male from songpost, a short series of very high, thin sharp whistles, rising and falling, mixed with scratchy and chattering notes, reminiscent of song of Dark-backed Weaver (*Ploceus bicolor*). Contact call a soft whistle; flight call a high "chink" or "spink".
Habitat. Montane forest in high-rainfall areas, also forest edges and clearings, and isolated copses of trees; at 1400–3000 m, mostly 1800–2500 m.
Food and Feeding. Primarily frugivorous; some insects taken. Fruits eaten include *Sapium*, *Olea*, *Bridelia*, *Eugenia capensis*, *Ocotea usambarensis*, *Urea hypselodendron*, *Rapanea pulchra*, *Ilex mitis*, *Macaranga neomildbreadiana*, *Polyscias fulva*. Forages primarily in canopy, picking fruit close at hand and seldom stretching for it; hawks alate termites (Isoptera). In flocks of up to c. 25 individuals, once more than 100; feeds in association with *P. femoralis*, *Poeoptera stuhlmanni*, *Onychognathus tenuirostris* and *Onychognathus walleri*, also with bulbuls (Pycnonotidae).
Breeding. Season Feb–Apr in Sudan and Ethiopia, Apr–Jun in W Kenya and Oct–Dec in Tanzania; likely (on basis of breeding condition of specimens) Mar–Apr in DRCongo. Nest a lining of moss placed in tree hole up to 15 m above ground. One nest contained clutch of 3 eggs. No other information.
Movements. Presumed resident, but local movements likely. Absence from Rwandan forest during Oct–Dec suggests some seasonal movements.
Status and Conservation. Not globally threatened. Locally common to uncommon. Fragmented distribution in mountains, with isolated records in W & SW Tanzania. Single record from Mafinga Mts, in extreme NE Zambia; status there unclear.
Bibliography. Beesley (1972), Benson (1946b), Brown, P. (1972), Carswell *et al.* (2005), Chapin (1954), Dorst & Roux (1973), Dowsett, Aspinwall & Dowsett-Lemaire (2008), Dowsett, Berry & Foot (2003), Dowsett-Lemaire (1990), Fry *et al.* (2000), Jackson & Sclater (1938), Moermond (1992), Moermond *et al.* (1993), Moreau & Sclater (1938), Nikolaus (1987), Taylor & Taylor (1988).

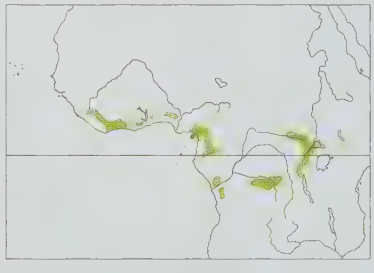
106. **Abbott's Starling**

Pholia femoralis

French: Choucador d'Abbott **German**: Abbottstar **Spanish**: Estornino de Abbott

Taxonomy. *Pholidauges femoralis* Richmond, 1897, Mount Kilimanjaro, Tanzania.
Genus often subsumed into *Cinnyricinclus*. Has been suggested that this species and *P. sharpii* form a superspecies. Monotypic.
Distribution. Highland forest in SC Kenya (E of Rift Valley) and NE Tanzania.

Descriptive notes. 17 cm. Small starling with distinctive plumage pattern. Head, entire upperparts, and chin, throat and breast are blue-black with slight sheen; wing and tail glossy blue-black; belly, flanks and undertail-coverts creamy white; iris whitish; bill and legs black. Sexes alike (erroneous descriptions in the literature based on subadult female). Juvenile is dark grey above, yellowish wash on throat and breast, dark shaft streaks on throat, breast and belly, iris dark brown. Voice. Song described as high-pitched and squeaky, with twanging notes; whistling 6-note call, 3 notes ascending and then 3 descending, may be a song or a contact call. Very high-pitched metallic calls.
Habitat. Montane forest, favouring areas of tall trees with discontinuous canopy; 1800–2600 m, ranging up to 2800 m.
Food and Feeding. Diet fruit and insects; fruit of *Cornus volkensii* recorded. Feeds chiefly in canopy, hawks insects and gleans foliage. In small flocks.
Breeding. Breeding records in Feb, Mar and Oct in Tanzania. Nest in tree hole, including old woodpecker (Picidae) hole; two broods of two nestlings recorded; chicks fed with insects by both adults. No other information.
Movements. Resident. Local movements related to fruiting of trees, with fluctuations in numbers and periodic absence from particular areas; possibly some substantial movements between forests.
Status and Conservation. VULNERABLE. Rare within small range. Some evidence of population decline at sites where formerly categorized as common. In Kenya, generally scarce and local on Mt Kenya; few recent records from Kikuyu Escarpment Forest in S Aberdare Mts, where formerly common (flocks of up to 40 observed); recorded also in Chyulu Hills (no recent records; old records of feeding flocks of up to 100 individuals) and Taita Hills. In Tanzania, quite common above 1800 m on Mt Kilimanjaro in 1977 but few recent records, and regarded as probably rare in 1991; recorded also on Mt Meru, where scarce and possibly only seasonal in occurrence; flocks of 20–25 observed at 1600 m in Kindoroko Forest Reserve, in N Pare Mts in 1993. Continuing forest loss and degradation remain major threats; little highland forest is adequately protected within the species' range. Recent surveys suggest that it is restricted to forest sections with least human disturbance.
Bibliography. Anon. (2008b), Butchart & Stattersfield (2004), Fry *et al.* (2000), Moreau (1935), Otieno *et al.* (2007), Taylor & Taylor (1988), Thomas (1962), van Someren (1939), Stattersfield & Capper (2000), Zimmerman *et al.* (1996).



Genus *POEOPTERA* Bonaparte, 1854

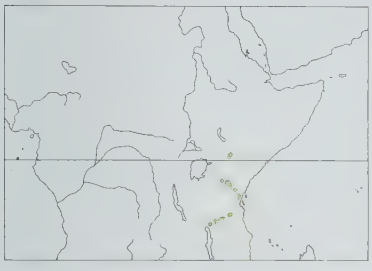
107. **Narrow-tailed Starling**

Poeoptera lugubris

French: Choucador à queue étroite **German**: Spitzschwanzstar **Spanish**: Estornino Rabilargo

Taxonomy. *Poeoptera lugubris* Bonaparte, 1854, no locality = Gabon.
Monotypic.
Distribution. E Sierra Leone, N & E Liberia and S Ivory Coast; S Ghana, SW Togo, Nigeria and Cameroon S, including Bioko I (Fernando Póo), to Gabon, PRCongo and NW Angola (Cabinda S to Cuanza Norte); and SW, SC & NE DRCongo and SW Uganda.

Descriptive notes. 18 cm; 35–43 g. Small, slim, dark starling with very long, narrow, graduated tail. Male is uniformly dark glossy blue except for remiges and tail, which are black with slight gloss; iris yellow; bill and legs black. Female has body plumage grey, slight blue gloss on dorsal surface; remiges brown, chestnut patch on inner webs of primaries; tail black, proportionally shorter than in male; bare parts as for male. Juvenile resembles female but duller, with less gloss, chestnut primary patch in both sexes, tail shorter, iris dark. Voice. Flight call a shrill, cheeping in chorus; also melodious whistling calls, which are possibly contact calls.
Habitat. Lowland forest, ranging out into forest patches; also coffee plantations, regenerating patches of cultivation and old clearings with high canopy cover. Below 1000 m in Cameroon, up to 1700 m in Uganda.
Food and Feeding. Diet primarily fruit, also insects. Fruits including *Musanga*, *Rauwolfia*, *Macaranga*; also arils of *Pycnanthus*. Insects recorded in diet are butterflies (Lepidoptera), flies (Diptera), alate termites (Isoptera), flying ants (Formicidae) and beetles (Coleoptera). Forages predominantly in canopy. Most insects captured by hawking. Feeding flocks generally of 10–40 individuals, rarely up to 100; sometimes joins mixed-species flocks of frugivores, and foraging party seen with Grey-throated Barbets (*Gymnobucco bonapartei*) and White-headed Woodhoopoes (*Phoeniculus bollei*), the latter an insectivorous species. Regular roost of c. 40 individuals in village near Mt Kupe (Cameroon) in Nov each year; communal roosts noted in Congo Basin.
Breeding. Season Dec–Jan in Liberia, Jan in Nigeria and Cameroon, Dec–Mar in Gabon and Feb–Mar in Angola; in DRCongo, Dec in NE (Ituri region) and Mar and Jun–Jul in E (Kivu); Feb in Uganda. Colonial breeder. Nest in tree hole 5–8 m above ground; apparently dependent on holes provided by colonial-breeding Naked-faced Barbet (*Gymnobucco calvus*) and other members of this genus (e.g. Grey-throated Barbet), and in Uganda both barbet and starling nests found in trees utilized also by Grey-cheeked Hornbills (*Bycanistes subcylindricus*); trees apparently shared amicably, but in Cameroon present species was chased off in Mar (when barbets nesting) but tolerated in May. Clutch in one nest 3 eggs, pale blue-grey with sparse brown spots (obtained



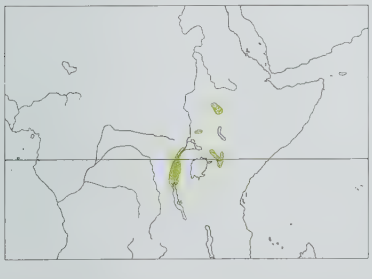
when tree felled); incubation probably by female alone (at colonies, only females seen to have bent tail); chicks fed by both parents. No further information.
Movements. Presumed resident; movements related to fruiting patterns of forest trees likely.
Status and Conservation. Not globally threatened. Not uncommon to scarce and local; locally common in Angola. Few records in Ghana and Togo, and uncommon in Nigeria. Recorded in SW Central African Republic, but status there unclear. Has extensive, but discontinuous, range in lowland forest.
Bibliography. Baranga & Kalinga (1991), Borrow & Demey (2001), Bowden (2001), Brosset & Érard (1986), Carswell *et al.* (2005), Chapin (1954), Dean (2000b), Dean *et al.* (1987), Eisentraut (1963), Fry *et al.* (2000), Gatter (1997), Germain *et al.* (1973), Heinrich (1958), Prigogine (1971), Serle (1940, 1954).

108. **Kenrick's Starling**

Poeoptera kenricki

French: Choucador de Kenrick **German**: Kenrickstar **Spanish**: Estornino de Kenrick

Taxonomy. *Paeoptera* [sic] *kenricki* Shelley, 1894, Usambara Mountains, Tanzania.
May form a superspecies with *P. stuhlmanni* and has been considered conspecific. Birds from Kenya described as race *bensoni*, supposedly larger than those in Tanzania; overlap in measurements, however, apparently considerable, and recognition of geographical races considered unwarranted. Monotypic.
Distribution. Mountains in C Kenya and NE & E Tanzania (Eastern Arc).



Descriptive notes. 15 cm; 46–54 g. Small, dark starling. Male is uniformly black with slight bronzy sheen; iris pale yellow; bill and legs black. Female has head, throat, breast and belly grey, upperparts, wing and tail dark charcoal-grey; chestnut patch on inner web of primaries, also on outer web of primaries P1–P8; iris yellow; bill and legs black. Juvenile has sooty plumage, with chestnut on primaries in both sexes. Voice. Musical babble from flocks; loud sweet "peleep" a possible flight call.
Habitat. Highland forests, generally in areas of high rainfall, at 900–2500 m; visits isolated forest patches. In Tanzania, recorded also at 450 m in E Usambaras, where found at forest edges or in agricultural smallholdings.
Food and Feeding. Exclusively frugivorous; *Ficus* and *Trema* recorded in diet. Feeds in canopy, in noisy flocks of 16–30 individuals, often with *Onychognathus walleri*.
Breeding. Recorded in Jan, Mar–May, Jun–Jul and Sept–Nov; main season in Oct. Nest in tree hole; seen at old holes of woodpecker (Picidae) and barbet (Capitonidae). No other information.
Movements. Very poorly known. Apparently nomadic, wandering widely; possible altitudinal movements in Eastern Arc forests of Tanzania.
Status and Conservation. Not globally threatened. Restricted-range species: present in Tanzania-Malawi Mountains EBA and in Kenyan Mountains EBA. Fairly common but local. Poorly known species, for which there is very little biological information.
Bibliography. Amadon (1956), Borghesio *et al.* (2008), Bowen (1931a), Brown (1965), Brown & Britton (1980), Burgess & Mlingwa (2000), Fry *et al.* (2000), Fuggles-Couchman (1984), Fuggles-Couchman & Elliott (1946), Lack (1936), Sclater & Moreau (1933), Zimmerman *et al.* (1996).

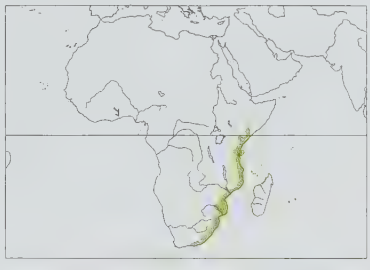
109. **Stuhlmann's Starling**

Poeoptera stuhlmanni

French: Choucador de Stuhlmann **German**: Stuhlmannstar **Spanish**: Estornino de Stuhlmann

Taxonomy. *Stilbopsar stuhlmanni* Reichenow, 1893, Badjua, on plateau west of Lake Albert, DRCongo.
May form a superspecies with *P. kenricki* and has been considered conspecific. Monotypic.
Distribution. SW Ethiopia, S Sudan (Imatong Mts), extreme E DRCongo, SW Uganda, Rwanda and Burundi, Mt Elgon (Uganda–Kenya border), W Kenya and W Tanzania (W of Rift Valley).

Descriptive notes. 15 cm; 38–46 g. Small, dark starling. Male has head, nape, and chin to breast dark blue-black with blue sheen; upperparts and belly, flanks, thighs and undertail-coverts black with purple sheen; wing and tail black; iris yellow outer ring, dark brown inner ring; bill and legs black. Female is dark grey, with bluish sheen on head, nape, throat and breast, slight purple gloss on back and blue gloss on rump; centre of belly, thighs and undertail-coverts matt grey; wing and tail black, inner webs of all primaries and outer webs of primaries P1–P8 chestnut-brown; iris with yellow outer ring, bill and legs black. Juvenile resembles female, but browner upperparts, grey-brown underparts, both sexes with chestnut primary patch, iris brown. Voice. Song a string of whistles and chuckles. Contact call musical "prtlee" or variants, typically disyllabic or trisyllabic.
Habitat. Highland and montane forest, generally at 1500–2600 m.
Food and Feeding. Diet apparently entirely fruit, including *Ficus*, *Trema*, *Urera*, *Olea*, *Sapium*, *Schefflera*, *Ilex mitis*, *Macaranga neomildbreadiana*, *Alangium chinense*, *Polyscias fulva*, *Maesa lanceolata*. Forages primarily at middle levels and in canopy. In pairs and small groups; not a member of mixed-species flocks in Itombe region of DRCongo, but elsewhere seen feeding in flocks alongside bulbuls (Pycnonotidae), white-eyes (Zosteropidae) and barbets (Capitonidae); sometimes with flocks of *Onychognathus walleri*.
Breeding. Breeds Mar in Ethiopia, Apr in Sudan, Feb–Mar in Uganda and Jun in E DRCongo (Kivu region); recorded Dec and Mar in Kenya. Nest in tree hole at least 10 m above ground. No other information. Pair in Kenya seen to chase *Indicator* honeyguide, suggesting that brood parasitism may occur.
Movements. Presumed resident, with local movements related to fruiting patterns.
Status and Conservation. Not globally threatened. Common within its limited range.
Bibliography. Brown (1975), Carswell *et al.* (2005), Chapin (1954), Cunningham-van Someren (1975), Dowsett-Lemaire (1990), Fry *et al.* (2000), Jackson & Sclater (1938), Moermond *et al.* (1993), Nikolaus (1987), Prigogine (1971), Zimmerman (1972).



Genus *NOTOPHOLIA* Roberts, 1922

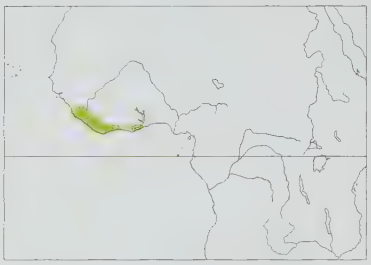
110. **Black-bellied Glossy Starling**

Notopholia corrusca

French: Choucador à ventre noir **Spanish**: Estornino Ventrinegro
German: Schwarzbauch-Glanzstar
Other common names: Black-bellied Starling, Black-breasted Glossy Starling

Taxonomy. *L[amprotornis] corrusca* Nordmann, 1835, Southern Africa = Eastern Cape, South Africa.
Genus often subsumed into *Lamprotornis*. Two subspecies recognized.
Subspecies and Distribution.
N. c. corrusca (Nordmann, 1835) – S Somalia S in narrow belt along coast to Kenya, Tanzania, Mozambique and E South Africa, extending inland along some major rivers (thus reaches extreme SE Zimbabwe).
N. c. vaughani (Bannerman, 1926) – Pemba I, off NE Tanzania.

Descriptive notes. 18 cm; 51–68 g. Rather small and short-tailed, dark starling. Male nominate race has crown, nape and mantle glossy dark green, some iridescent blue on ear-coverts; back, rump and uppertail-coverts dark green with violet-blue gloss; wing dark blue-green with some gloss, outer edges of primaries violet-blue; tail dark violet-blue; chin, throat and upper breast glossy dark green, lower breast and belly dark violet-blue with bronzy sheen, thighs dark green with violet-blue gloss; iris orange-yellow, but red for variable period during breeding (when handled, can also change colour of only one eye at a time, presumably by redirecting blood circulation); bill and legs black. Female is like male, but lower breast and belly matt black without gloss. Juvenile is sooty black, lacking gloss, with iris grey. Race *vaughani* is larger than nominate, with entire head glossy purple, instead of greenish. Voice. Song a sustained jumble of trilling and piping notes, harsher and less musical than that of *Lamprotornis nitens*; mimicry of at least ten other bird species reported from Zanzibar, Mozambique and South Africa. Flight call a single nasal note; alarm call harsh "jaaa".
Habitat. Coastal forest and dense vegetation, in E Usambaras (Tanzania) primarily on forest edge or agricultural smallholdings; on Pemba I, race *vaughani* regular in forest and coral-rag scrub, absent from farms and clove (*Syzygium aromaticum*) plantations. Lowlands below 500 m, but to 1000 m in E Usambaras and to at least 2000 m in Meru forests (EC Kenya).
Food and Feeding. Diet primarily fruit, also nectar, also insects and other small animals. Many fruits taken: *Ficus*, *Clerodendron myricoides*, *Lantana*, *Sapium manianum*, *Clausena anisata*, *Grevillea*, *Dovyalis longispina*, *Euclea natalensis*, *Trema orientalis*, *Halleria lucida*, *Ekebergia capensis*, *Apodytes dimidiata*, *Mimusops caffer*, *Sideroxylon inerme*, *Rotheca myricoides*, *Protorhus longifolia*, *Commiphora harveyi*, *Rauwolfia membasiana*, *Beinbollia borbonica*, *Croton sylvaticus*, *Antidesma venosum*, *Margaritoria discoidea*, *Bridelia micrantha*, *Melia azederach*, *Olea capensis*, *Osyris lanceolata*, *Acacia cyclops*, *Rapanea melanophloeos*, *Morus*, *Harpephyllum caffrum*, *Trichilia emetica*, *Phoenix reclinata*, *Acokanthera oppositifolia*. Nectar of *Aloe marlothii* taken. Animal food items include reed frogs (*Hyperolius*), small lizards, snails (Gastropoda), flying ants (Formicidae) and alate termites (Isoptera). Forages mainly in trees, but also on ground. In small to medium-sized flocks.
Breeding. Season Oct–Jan throughout range, with occasional breeding records in other months. Monogamous. Nest a lining of grass, hair, feathers and dry leaves placed in tree hole, either natural hole or old hole of barbet (Capitonidae) or woodpecker (Picidae), 2·5–6 m above ground; one nest recorded in a building. Clutch 2–4 eggs, pale greenish-blue, rarely with faint brown spotting; only female incubates, male perching nearby and warbling, chicks fed by both sexes; no information on duration of incubation and nestling periods.
Movements. Presumed resident on Pemba (race *vaughani*); birds on Zanzibar not distinct, implying interchange with other populations. Elsewhere no regular pattern of seasonal movement, and in many areas present all year, although numbers fluctuate dramatically. Inland in Mozambique and Zimbabwe apparently a breeding visitor; at W limit of range in South Africa a winter visitor, common only during fruiting periods of *Rapanea melanophloeos*. N–S movements along E African coast seem likely.
Status and Conservation. Not globally threatened. Locally common, and abundant in some areas. Wide-ranging. Estimated population exceeding 10,000 individuals in C & S Mozambique. Possibly only a non-breeding visitor in Somalia.
Bibliography. Amadon (1956), Ash & Miskell (1998), Bleher *et al.* (2003), Borghesio *et al.* (2008), Britton & Britton (1970), Catry *et al.* (2000), Chittenden & Myburgh (1994), Craig (1989, 1997b), Frost (1980), Fry *et al.* (2000), Gilges (1945), Hockey *et al.* (2005), Holland (1945), Koen (1992), Lack (1936), McCulloch (1963), Nixon (1992), Oatley & Skead (1972), Odgers (1993), Pakenham (1936, 1979), Parker (1999, 2005), Pinto & Lamm (1956), Pooley (1967), Swynnerton (1908), Tree (1986), Vernon (1973, 1993).



Genus *HYLOPSAR* Boetticher, 1940

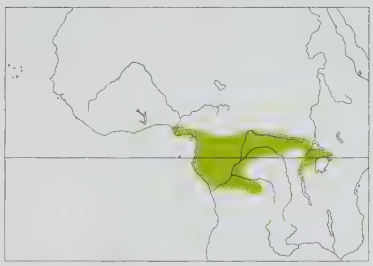
111. **Copper-tailed Glossy Starling**

Hylopsar cupreocauda

French: Choucador à queue bronzée **German**: Kupferglanzstar **Spanish**: Estornino Colicobrizo
Other common names: Copper(y)-tailed Starling

Taxonomy. *Lamprocolius cupreocauda* Hartlaub, 1857, Sierra Leone, Aguapim (SE Ghana) and Gabon [error].
Genus often subsumed into *Lamprotornis*. Forms a superspecies with *H. purpureiceps*. Monotypic.
Distribution. Sierra Leone, SE Guinea, Liberia, Ivory Coast and Ghana.

Descriptive notes. 18 cm; 51–66 g. Fairly small, dark starling with shortish tail. Crown and nape are turquoise blue with purple sheen, mantle, back and wing turquoise blue, rump and tail glossy bronze; chin, throat and upper breast purple, passing into turquoise blue on lower breast, belly and flanks; undertail-coverts matt charcoal, some feathers with violet tips; iris yellow; bill and legs black. Sexes alike. Juvenile is matt charcoal-grey, some gloss on wings and tail, iris initially dark. Voice. Song described as a jumble of harsh notes. Flight calls harsh, grating notes.
Habitat. Primary lowland evergreen forest, including forest edge and gallery forest; observed also in logged forest, plantations and areas of shifting cultivation in forest zone.
Food and Feeding. Diet insects and fruit, latter including *Ficus* and *Rauwolfia*. Forages chiefly in canopy; searches for insects also in middle storey of forest. In pairs and small groups; occasionally joins mixed-species flocks of insectivores.
Breeding. On basis of activity at nest-holes and presence of juveniles, season Oct–Dec in Sierra Leone and Liberia, Nov and Jan in Ivory Coast and Aug in Ghana. Nest in hole up to 15 m above ground in tree, apparently favouring dead emergent or relict trees. Adult observed accompanied by three fledglings. No other information.
Movements. Presumed resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Generally common to not uncommon; probably declining. Density of 2–4 pairs/km² recorded in mature forest in Liberia. In Ivory Coast, abundant in Taï Forest National Park, and quite common in 1980s in Yapo Forest; recently noted as being fairly common in Mt Péko National Park. Appears common and widespread in Ghana, but only small flocks of 5–10 individuals observed in recent surveys. Restricted to Upper Guinea forests of W Africa, where deforestation continues throughout range. Civil war and political instability have compromised the security of forest reserves in the region.
Bibliography. Allport *et al.* (1989), Anon. (2008b), Borrow & Demey (2001), Butchart & Stattersfield (2004), Colston & Curry-Lindahl (1986), Dutson & Branscombe (1990), Fry *et al.* (2000), Gartshore (1989), Gatter (1997), Stattersfield & Capper (2000), Thiollay (1985), Walker (1939).



112. **Purple-headed Glossy Starling**

Hylopsar purpureiceps

French: Choucador à tête pourprée **German**: Samtglanzstar **Spanish**: Estornino Cabecipúrpura

Other common names: Purple-headed Starling, Velvet-headed Glossy Starling

Taxonomy. *Lamprocolius purpureiceps* J. Verreaux and É. Verreaux, 1851, West Africa = Gabon.
Genus often subsumed into *Lamprotornis*. Forms a superspecies with *H. cupreocauda*. Monotypic.
Distribution. S Nigeria and S Cameroon E to S Central African Republic, Uganda and W Kenya, S to N Angola (Cabinda) and SW, N & NE DRCongo.

Descriptive notes. 18 cm; 50–79 g. Fairly small, short-tailed dark starling. Crown, chin, throat and chest are deep glossy purple, sharply demarcated from adjacent plumage areas; nape, mantle, back and rump glossy greenish-blue; wing iridescent blue, shading to violet on outer margins of primaries; tail black with faint purple gloss; belly and flanks glossy greenish-blue, undertail-coverts black with blue or bronze sheen; iris dark brown; bill and legs black. Sexes alike. Juvenile is matt charcoal-grey, except for some gloss on wings. Voice. Song apparently a series of short, musical calls; sings in chorus, and imitations of Common Bulbul (*Pycnonotus barbatus*) and Chestnut Wattle-eye (*Dyaphorophyia castanea*) reported. Flight call a metallic "twink".
Habitat. Evergreen lowland forest, generally to 1500 m; to 1800 m in E of range.
Food and Feeding. Mainly frugivorous; some animal food also taken. Fruits consumed include those of *Ficus*, *Rauwolfia*, *Heisteria*, *Musanga*, *Pycanthus*, *Morinda*, *Xylopia*, *Allophyllus*, *Macaranga*, *Polyalthia*, *Trichoscypha*. Small snail (Gastropoda) and insects, including termites (Isoptera), caterpillars (Lepidoptera), grasshoppers (Orthoptera) and mantids (Mantodea), reported in stomach contents. Forages primarily in canopy. Mostly in pairs or in groups of 4–5 individuals, rarely in flocks exceeding 100 birds; joins mixed-species flocks of frugivores. Dominated by *Lamprotornis splendidus* and by hornbills (Bucerotidae); in presence of these, forages lower down, in understorey.
Breeding. Breeds Mar in Cameroon and Dec–Feb in Gabon; in DRCongo, Jun–Oct in NE and Dec–Mar in Kivu region; Apr in Uganda. Monogamous. Nest in tree hole up to 26 m above ground; hollow of one nest lined with small pieces of green leaves. In one nest, clutch of 3 eggs, blue with brown spotting forming a ring at thicker end; at another nest chicks fed by both adults. No other information.
Movements. Presumed resident, with local movements related to fruit availability.
Status and Conservation. Not globally threatened. Locally common in much of range; not uncommon in Cabinda (N Angola). Record from Benin in 1998. Widely distributed in lowland forest. Reported occurrence in Guinea and W Ivory Coast, where similar *H. cupreocauda* found, requires corroboration.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family PASSERIDAE (OLD WORLD SPARROWS)

- Small passerines with thick, pointed, conical bill, broad and mostly blunt wings, and relatively short tail; plumage various combinations of brown, chestnut, grey and white, most with some black areas, some also with yellow.
- 12–17·5 cm.

- Afrotropical, Palearctic and Oriental Regions.
- Open country, villages and urban areas.
- 6 genera, 40 species, 101 taxa.
- No species threatened; none extinct since 1600.

Systematics

The systematics of the family Passeridae have been controversial. The linguistic confusion arising from the English vernacular names of "weaver finches" and "passerine finches", the latter included in the large seed-eating grouping of the "Old World finches", has added to the problem. These names imply relationships with particular families, the finches (Fringillidae) and the weavers (Ploceidae), respectively. The use of the term "sparrow" by the early English-speaking settlers in North America as a substantive name for many species of bunting (Emberizidae) has not helped. In the argument leading to their present classification, the term "Old World sparrows" is employed to describe the taxon including the "true" sparrows, the rock-sparrows, the bush-sparrows, the snowfinches and the ground-sparrows.

Old World sparrows are seed-eaters and, apart from recent introductions, they are confined to the Old World, where they are found in the continents of Africa, Europe and Asia. This suggests that they are more likely to be related to the Old World seed-eating families with ten primaries, namely the weavers, the waxbills (Estrildidae) and the indigobirds (Viduidae), than to the largely New World families of the finches and the buntings and allies with nine primaries, although it is not clear if these two groups of seed-eating birds are related to one another evolutionarily or merely through convergence to a common way of life.

Linnaeus, in his *Systema Naturae* of 1758, attempted a classification illustrating the relationships among species. This was, in fact, a classification based on a creationist concept, rather than an evolutionary one. The relationship between these two concepts in classification, the one based on physical resemblances owing to shared characteristics, termed the "phenotypical species concept", and the natural or evolutionary one based on perceived biological relationships, the "biological species concept", still exists, and it results in disagreement about the systematics, although the two apparoaches, in theory, have the same goal.

In 1758 Linnaeus listed only two species of Old World sparrow, the House Sparrow (*Passer domesticus*) and the Eurasian Tree Sparrow (*Passer montanus*), but in 1766 he added two more, the Common Rock-sparrow (*Petronia petronia*) and the White-winged Snowfinch (*Montifringilla nivalis*). These four species, covering the three well-recognized genera of this family, were all given the generic name *Fringilla*, or "finch", although it should be noted that Linnaeus did not recognize any groupings between order and genus, the term "family" not coming into use until after 1800. The generic name of *Passer* was adopted for the House and Eurasian Tree Sparrows in 1760, *Montifringilla* for the snowfinch in 1828 and *Petronia* for the Common Rock-sparrow in 1829, but these birds were still considered by implication to be finches, and they were listed as such by R. B. Sharpe in his 1888 *Catalogue of Birds in the British Museum*, although, nearly 40 years earlier, F. de Lafresnaye had suggested that the *Passer* sparrows might be allied with the weavers on the grounds of similarities between the two in nest construction and breeding biology. Things changed in the twentieth century, leading J. M. Winterbottom to make the following statement in 1966: "The classification of the thick-billed seed-eating passerines and their allies has been one of the most controversial aspects of avian systematics today."

The true sparrows in the genus Passer *share many characteristics. They are similar to each other in size, body structure and behaviour, and are gregarious and social in almost every aspect of their lives. In most species, like the* ***House Sparrow****, males have strongly patterned heads and black bibs, which are lacking in females. The House Sparrow is considered to have evolved only 10,000 years ago, when humans first formed settled farming communities. This association has continued ever since. Altogether, 17 of the 26* Passer *sparrows have been recorded nesting on buildings and feeding in and around human settlements.*

[*Passer domesticus parkini*, Gujarat, India.
Photo: Amano Samarpan]

Apart from recent introductions, the Passeridae are confined to the Old World continents of Africa, Europe and Asia. Evidence suggests an Afrotropical origin for the genus Passer, *about 40 million years ago, and they may have spread to Eurasia around two million years ago, where they were separated into isolated populations by the Pleistocene glaciations, giving rise to the different species. The* ***Russet Sparrow*** *probably evolved from a population trapped in an ice-free refugium in the Yangtze Valley during the last Pleistocene glaciation, 25,000–15,000 years ago.*

[*Passer rutilans*, Sat Tal, Uttarakhand, India. Photo: Marc Guyt/AGAMI]

In the 1920s, P. P. Sushkin followed Lafresnaye, not only on the grounds of nest construction, but also because of the structure of the horny palate and the course of the moult, although, in hindsight, not very convincingly, and he suggested that the Old World sparrows should be transferred to the weavers as a distinct subfamily, Passerinae, that had evolved from the sparrow-weavers (*Plocepasser*). Sushkin specifically mentioned that the genera *Passer*, *Petronia* and *Montifringilla* were intimately related, exhibiting similarities in skeletal structure, relief of the palatal surface of the horny bill, a complete post-juvenile moult and nest architecture. This suggestion was adopted in the major bird classifications by C. Vaurie in 1959 and in J. L. Peters's *Check-list of Birds of the World* in 1962, although not without some dissension. G. L. Bates, for example, objected on the grounds that, on sparrows, the outermost remix is displaced to the dorsal surface of the wing, as it is on finches and buntings. As early as 1948, D. A. Bannerman, on the basis of doubts about the true affinity of the sparrows, suggested, with considerable perspicacity, that they should be treated as distinct from the Fringillidae and the Ploceidae and be given full family rank. Since then, there have been increasing suggestions that the Old World sparrows, particularly *Passer*, be considered a separate family, although, even as late as the 1970s, doubts were still being expressed about the composition of this family. For example, on the basis of examination of the karyotypes (the appearance of the chromosomes in a somatic cell of a species), N. S. Bulatova and colleagues considered that *Montifringilla*, then including *Pyrgilauda*, and *Petronia* were closer to the finches than they were to the *Passer* sparrows. In contrast, T. N. Pocock pointed out that the presence of certain small foramina in the posterior wall of the orbit argued in favour of *Petronia* being related to *Passer*. Although this character has been shown to have little taxonomic value, it does illustrate the trend in thinking, even though many of the criteria used at the time have subsequently proved to be of dubious worth. A more convincing study of the appendicular mycology, undertaken by G. D. Bentz, indicated that the three genera *Passer*, *Petronia* and *Montifringilla* are, indeed, closely related.

Further support for the separation of the sparrows is given by recent biochemical investigations by C. G. Sibley and his coworkers. These have involved electrophoretic patterns of egg-white proteins and a long series of experiments with DNA–DNA hybridization. The somewhat contradictory evidence from the egg-white proteins, in which the five species of *Passer* investigated differed from the ploceids, led Sibley to the conclusion that a distinct family, Passeridae, should be recognized, although he considered that the relationship of the snowfinches was probably not with the sparrows. This view was, however, revised in the light of the DNA–DNA hybridization work, with the sparrows relegated to a subfamily Passerinae within a larger family Passeridae that included as other subfamilies not only the weavers, but also the wagtails and pipits (Motacillidae), the accentors (Prunellidae) and the waxbills. In this later work, *Montifringilla* is restored to its position with *Passer* and *Petronia*, and the Old World sparrows are considered to be the most primitive of all the subfamilies on the basis of bill structure, biochemical evidence and pterylosis, having separated from the ploceids about 36 million years ago, the time marker being the separation of the flightless ostriches (Struthionidae) and rheas (Rheidae) 80 million years ago by the splitting of Africa and South America, coupled with the assumption that DNA evolution proceeds at a uniform rate in birds.

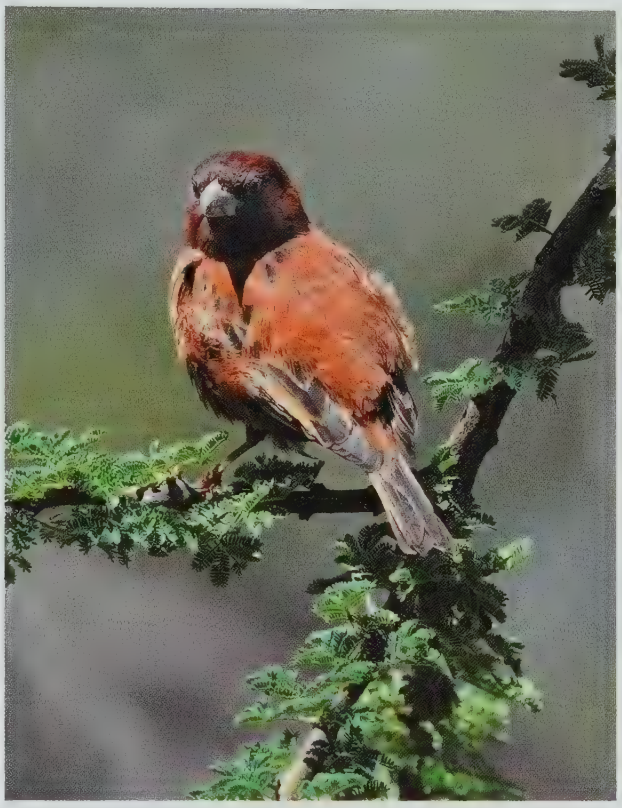
The sparrows probably originated in a semi-arid to arid grassland habitat with scattered trees. This is still the typical habitat for many of the true sparrows. Some however, including the ***Saxaul Sparrow****, have moved into desert or semi-desert. This species is particularly associated with saxaul trees* (Haloxylon ammodendron), *whose seeds are an important food for this sparrow. The Passeridae have the thick, conical bills typical of seed-eating passerines. The bills of male* Passer *sparrows become black in the breeding season, and are horn-coloured at other times.*

[*Passer ammodendri*, Mongolia. Photo: Roland Seitre]

An earlier investigation by V. Ziswiler on the technique of dehusking the seeds, the structure of the horny palate and the morphology of the alimentary tract provided good evidence for separating the Old World sparrows from the finches, but it was not conclusive with regard to their relationship with the weavers. More thorough investigation of the structure of the tongue, carried out by W. J. Bock and J. J. Morony, has given the best evidence for placing them in a separate family. These workers found a unique skeletal structure in the tongue which they named the preglossale, a new feature of complex structure that was, in their opinion, clearly a derived character that is lacking in the weavers and finches and hence of significant taxonomic value, and which was already present in the ancestors of the Old World sparrows. Sibley and J. E. Ahlquist countered that the preglossale may have been present in the ancestor of all the ploceids, but lost in all except the Passerinae, although this sounds a little like special pleading.

In addition to the caveat by Sibley regarding the preglossale, there are some other unresolved discrepancies. Taxonomy depends on perceived relationships, but the problem lies in differentiating between those characters that show genuine relationships and those that are the result of convergence. The fossil record provides little help in elucidating the systematics of the sparrows, but it does provide some ideas on their evolutionary history. The earliest fossil comes from the Oligocene in Africa, 38–24·6 million years ago, close to the figure suggested by Sibley for the separation of the Passerinae ancestor. The family Passeridae is, apart from recent introductions, entirely confined to the Old World, with the snowfinches and ground-sparrows restricted to higher altitudes in Eurasia, mainly in Asia.

The true sparrows, those in the genus *Passer*, form a homogeneous taxon, its members sharing a large number of characteristics. They are almost entirely social species, similar to each other in size, body structure and behaviour; for example, they are among the very few groups of birds that indulge in both bathing in water and dusting in sand or dust. Almost all breed in colonies or loosely colonial groups. Many are associated with man, his animals and his agricultural crops, and frequently nest on man-made buildings; the nests, whether free-standing in trees or in cavities, are domed over. The bill of the males becomes black in the breeding season, and in some of the species so also does that of the females; the bill of some species is black throughout the year. Three of the 26 species, the Sudan Golden Sparrow (*Passer luteus*) and the Arabian Golden Sparrow (*Passer euchlorus*), both formerly placed in the genus *Auripasser*, and the Chestnut Sparrow (*Passer eminibey*), formerly placed in a monotypic genus *Sorella*, are now accepted as belonging to the genus *Passer*.



There is compelling evidence for an Afrotropical origin of the true sparrows, genus *Passer*, about 40 million years ago. The first evidence for *Passer* in Eurasia comes from fossil remains in the Levant about 300,000 years before present, where presumably a true sparrow of the black-bibbed type, the type to which all the Eurasian *Passer* belong, spread from the Afrotropical Region during the upheaval associated with the transition from the Pliocene to the Pleistocene, some two million years ago. J. D. Summers-Smith has suggested that these birds colonized Eurasia, but were subsequently separated into isolated populations by the Pleistocene glaciations, giving rise to the different species of Eurasian *Passer*. Fossil sparrows identified as House Sparrows have been recorded from deposits in France dating to as early as 120,000 years before present, but it is doubtful if these can be other than House Sparrow precursors, as it is considered that *Passer domesticus* (*sensu stricto*) did not evolve until it developed its association with sedentary agricultural man about 10,000 years ago. These early European sparrows presumably were forced southwards by the Pleistocene glaciations to the Mediterranean, where they were isolated and consequently split into the House Sparrow in the east and the Spanish Sparrow (*Passer hispaniolensis*) in the west. Finally, the position of the Italian Sparrow (*Passer italiae*) has to be considered. This taxon has been treated as a subspecies variously of the House Sparrow and of the Spanish Sparrow, and it has even been suggested that all three taxa be merged into one species. More recently, however, D. Fulgione and co-authors have proposed that *italiae* is a separate species that has evolved from *hispaniolensis* and has secondarily made contact with *domesticus* in the Alpine region, giving rise to the current hybrid zone, although it has to be recognized that this still does not account satisfactorily for the broad zone of intermediates between "pure" *italiae* and "pure" *hispaniolensis* that extends from south of Naples, in southern Italy, to at least as far south as Malta.

It is generally accepted that the grey-headed sparrows of sub-Saharan Africa constitute a superspecies of five species that can

The five grey-headed sparrows of sub-Saharan Africa were previously lumped as the Common Grey-headed Sparrow (Passer griseus). *They are separated on the grounds that there are small areas where the different taxa overlap without interbreeding, as well as some minor differences in habitat choice and morphology. The* ***Parrot-billed Sparrow****, the largest member of this superspecies, is found in more arid country than the others of this group. Its heavy, arched bill gives it a distinctive "Roman-nosed" appearance. The grey-headed sparrows differ from their black-bibbed congeners in that the sexes are similar, and in both sexes the bill remains black throughout the year.*

[*Passer gongonensis*, Samburu National Park, Kenya.
Photo: Theodoulos Poullis]

*The rather colourful **Chestnut Sparrow**, and Arabian Golden* (Passer euchlorus) *and **Sudan Golden Sparrows**, were formerly assigned to separate genera, but are now accepted as belonging to* Passer. *These species have been described as "sesquimorphic", in that the plumage of the sexes is broadly similar, but the female is distinctly paler or duller. The Sudan Golden Sparrow has a chestnut mantle, scapulars and back, which are yellow in the Arabian species. The two golden sparrows form a superspecies, to which some authorities add the Chestnut Sparrow.*

Right: *Passer luteus*, Senegal. Photo: Roland Seitre]

be separated by the fact that there are small areas where the different taxa overlap without interbreeding, although they may intergrade in other parts. The rufous sparrows occur in six allopatric populations. The ones inhabiting the Cape Verde Islands, off the coast of West Africa, are now recognized as a distinct species; it is probable that these and the other five were separated by the same geological/climatic events as those that separated the grey-headed sparrows, but the rufous sparrows, being adapted to rather more arid conditions, have not yet come into contact again in the way that has happened with the less arid-loving grey-headed sparrows. On this basis, it seems sensible to treat the rufous sparrows as constituting six separate species belonging to a superspecies. This gives a total of 26 species in the genus *Passer*.

The six species of rock-sparrow were formerly lumped together in the genus *Petronia*, but current opinion recognizes that these are sufficiently distinct to be placed in three separate genera. The Pale Rock-sparrow (*Carpospiza brachydactyla*) differs from the others in its triangular-shaped wings, giving it an ap-

*The group of six rock- and bush-sparrows is divided into three genera, two of which are monotypic. The **Pale Rock-sparrow** differs from the others in its long triangular wings, which in flight give it an appearance more like a lark (Alaudidae) than a sparrow. Some authorities even suggest that it is not a sparrow at all, but a cardueline finch (Fringillidae), on the basis of its song, its nest and eggs, and the fact that its post-juvenile moult is only partial rather than complete as in other sparrows. However, its affinity with sparrows is supported by the structure of its horny palate and its digestive tract.*

[*Carpospiza brachydactyla*, Oman. Photo: Markus Varesvuo]

Although still often known as petronias, the rock-sparrows, or bush-sparrows of the genus Gymnoris *are more arboreal than the* Petronia *and* Carpospiza *species. They have relatively slender bills and narrow, slightly forked tails, and are much less social than the Common Rock-sparrow* (Petronia petronia). *The* ***Russet-browed Bush-sparrow****, also known as the Bush Petronia, is usually seen singly, in pairs, or in small family groups. Like others of the rock-sparrow group, with the exception of the Pale Rock-sparrow* (Carpospiza brachydactyla), *this species has a yellow spot on its throat, which is often inconspicuous.*

[*Gymnoris dentata dentata*, Wadi Saham, Yemen. Photo: Hanne & Jens Eriksen]

pearance in flight more like that of a lark (Alaudidae); it also builds an open cup-nest in a low bush. This and other characteristics, such as the fact that the post-juvenile moult is only partial, compared with the complete moult of other sparrows, have led H. Mendelssohn and others to suggest that it is not even a sparrow but, rather, a cardueline finch. Nevertheless, internal characteristics such as the cranium, and the structure of the horny palate and the digestive tract, confirm its relationships with the sparrows, although it is sufficiently distinct to be placed by itself in a separate, monotypic genus, *Carpospiza*. The story does not end there. The five remaining rock-sparrows fall into two distinct groups. One consists solely of the Common Rock-sparrow, which is confined to the Palearctic Region, is terrestrial in behaviour, and is associated with open, often barren, rocky ground. The second group contains the remaining four species, which occur widely over the Afrotropical, southern Palearctic and Oriental Regions and are more arboreal, living in open dry country with scattered trees, wooded savanna or open woodland; these are perhaps more appropriately termed "bush-sparrows" and are treated as belonging to a separate genus, *Gymnoris*, which is separated from *Petronia* on the basis of body structure and behaviour. *Petronia* has a short square tail with white terminal spots and longer wings, whereas the tail of *Gymnoris* is slender and slightly forked and lacks the white terminal spots; the bill of *Petronia* is heavy and conical, while that of *Gymnoris* is pointed and slender. *Petronia*, with its noticeably bouncy flight, is a highly social species, breeding mainly in loose colonies with up to 100 pairs, the nests at times separated by only a few metres. Its nest, usually placed in a crevice in a rock, a hole in an earth bank or a rodent burrow, is domed over like those of the *Passer* sparrows; it is largely terrestrial, and normally found in large flocks outside the breeding season. In contrast, *Gymnoris* species are much less social, at times in small flocks, but normally breeding in isolated pairs. They nest in tree cavities with usually only a pad of nest material, and are largely arboreal, using the pointed bill to obtain insects under tree bark, although they forage also on the ground.

Larger and more finch-like than the other members of Passeridae, the snowfinches differ further from them in that they predominantly run, rather than hop. They are confined to high altitudes, mainly in Asia, one species, the White-winged Snowfinch, extending its range to high elevations in the extreme south-west of Europe. Because of the general inaccessibility of their habitat, the snowfinches have, with the exception of the wide-ranging White-winged Snowfinch, received comparatively little study in the field until the last two decades. Until recently, all eight species were generally combined in the genus *Montifringilla*. They do, in fact, belong to two distinct groups. First, the three "true" snowfinches are confined to rocky habitats, which, as suggested by their vernacular name, they do not leave in the winter; furthermore, they fly freely, are loosely social, and roost and nest in crevices in cliffs or under rocks. The second group contains the five ground-sparrows, which differ in that they occupy an alpine steppe habitat, descend to lower levels in the winter, and are much more adapted to the ground than the snowfinches, running more than flying; they are territorial and tend to be associated with small rodents, in the burrows of which they roost, nest and seek refuge from predators.

Larger and stouter than others in the rock-sparrow group, the ***Common Rock-sparrow*** *differs from the* Gymnoris *bush-sparrows in its longer wings, its short, square tail with white terminal spots, and its heavy, conical bill. In contrast to the more arboreal* Gymnoris *species, it is generally found in bare, treeless country. Where the species in this group overlap in distribution, they tend to be separated by preferences for drier or more humid habitat.*

[*Petronia petronia petronia*, Lesvos, Greece. Photo: Mathias Schäf]

Larger and more finch-like than the other members of Passeridae, the snowfinches are more conspicuously patterned, have proportionately much longer wings and legs, and generally run rather than hop. The three Montifringilla *snowfinches remain at high altitudes throughout the year. They are mainly found in Asia, although the* ***White-winged Snowfinch*** *is found above the tree-line across southern Europe as far west as the Pyrenees. Snowfinches measure slightly longer than the rest of the Passeridae, at about 17 cm, but can be considerably heavier, at up to 57 g, as compared to 17–40 g for the rest of the family. The breeding male (above) of the nominate race of the White-winged Snowfinch has a bluish-grey head, separated from the black chin and throat by a short pale stripe, and rich chocolate brown upperparts. The non-breeding male (below) is much duller, with a brownish-grey head. The bill not only changes colour, from black in the breeding bird to horn-coloured, but, as can be seen here, is also longer in the summer, when insects are an important part of the diet. This seasonal change in bill length is characteristic of all members of Passeridae that have been studied. The longer wings of the snowfinches reflect the more aerial habits of these species, which include display-flights, and catching insects in flight.*

[Above: *Montifringilla nivalis nivalis*, Bern, Switzerland. Photo: Rolf Kunz.

Below: *Montifringilla nivalis nivalis*, Huesca, Spain. Photo: Javier Ara Cajal]

This has led some authorities, particularly A. Gebauer and his co-workers, to separate *Montifringilla* into two, or even three, distinct genera: the three snowfinches proper, which are increasingly being referred to as "snow-sparrows", are retained in *Montifringilla*, with the ground-sparrows, sometimes called "mountain steppe-sparrows", divided into the genera *Pyrgilauda* and *Onychostruthus*. The differences between the last two genera are somewhat marginal, and it would seem better to treat *Onychostruthus* as a synonym of *Pyrgilauda* pending further study.

The snowfinches are social species, breeding in small loose colonies in crevices in rocks, whereas the ground-sparrows are highly territorial, breeding in the abandoned burrows of rodent colonies or even in burrows that they have themselves excavated, using the bill and feet. The association of the latter with rodents is so close that it has even been suggested that they could be hosts of the bubonic plague bacterium (*Pasteurella pestes*), which is endemic within their geographical range. These burrows are used not only for nesting, but also for roosting, for shelter from the elements, and to escape from predators. Characteristic of many passerines living in open country, both the snowfinches and the ground-sparrows have songs that are a component of elaborate display-flights, as well as being given from a conspicuous perch, the latter particularly in the case of the snowfinches, which occur in rocky country, compared with the more steppe-like high plateaux inhabited by the ground-sparrows. The ground-sparrows not only forage on the ground, but also dig into the earth, and the dung of large mammals, in order to obtain invertebrate food. The snowfinches are considerably more aerial than the ground-sparrows, even to the extent of catching insects in flight.

The three snowfinches in the genus *Montifringilla* were once considered to represent a single species, or, alternatively, the Tibetan Snowfinch (*Montifringilla henrici*) was treated as a subspecies of the far more widespread White-winged Snowfinch or of the Black-winged Snowfinch (*Montifringilla adamsi*). It is, however, now recognized as being sufficiently distinct from the former to merit treatment as a full species, the more so as it overlaps in range with the latter, evidently without interbreeding, in a few areas. The three species are thought to form a superspecies.

V. V. Ivanitskiy suggested, in 1997, that some Passeridae had spread to the steppes of Asia in the Miocene, 25–5 million years ago, and in the orogeny of the later Tertiary separated into three genera. *Pyrgilauda* adapted to high-altitude steppe, and *Montifringilla* to high rocky mountain country, whereas *Petronia*, presumably including *Carpospiza* and *Gymnoris*, remained in lowland steppe and subsequently spread westwards, the bush-sparrows subsequently recolonizing Africa. The distribution of the snowfinches and ground-sparrows matches that of the accentors, which Sibley and Ahlquist, interestingly, considered to be more closely related to the ploceid weavers than to the genera *Passer* and *Petronia*.

Pending the resolution of where the Old World sparrows belong in relation to the other major seed-eating songbirds, the currently preferred arrangement is to treat them as a distinct family, Passeridae, with six genera. *Passer*, including the defunct *Auripasser* and *Sorella*, contains the true sparrows, a total of 26 species. *Carpospiza* is a monotypic genus, containing the Pale Rock-sparrow, while *Petronia*, another monotypic genus, houses the Common Rock-sparrow. *Gymnoris* contains four species of bush-sparrow, sometimes referred to as petronias; *Montifringilla*, the "typical" snowfinches, comprises three species; and, finally, *Pyrgilauda*, the ground-sparrows, consists of five species.

As already noted, there have been several recent taxonomic "splits", whereby taxa which were treated as subspecies are now considered to merit full species rank. In the Afrotropics, the five species forming the grey-headed sparrow superspecies were previously treated as conspecific, under the name *P. griseus*, and this is still preferred by some authorities. Similarly, the six species constituting the rufous sparrow superspecies have generally been combined in a single species under the name *P. motitensis*, and, again, some authorities maintain the latter arrangement.

Several other potential splits are worthy of consideration. For example, the eastern subspecies *yatii* of the Dead Sea Sparrow (*Passer moabiticus*) is a well-marked form, sometimes referred to as the "Afghan Scrub Sparrow" or "Yates's Sparrow". It has a small range, confined to the border regions of Iran, Afghanistan and Pakistan, is distinctive in morphology and plumage, and is geographically remote from other populations of the Dead Sea Sparrow. This eastern race was originally described as a separate species, but was subsequently merged with the western populations of the Dead Sea Sparrow. Whether *yatii* really does represent a separate species is undecided, but the possibility certainly merits investigation.

Another example concerns the Socotra Sparrow (*Passer insularis*), one of the six species forming the rufous sparrow superspecies. This species is presently treated as containing two subspecies, the nominate race on the main island of Socotra and the race *hemileucus*, found on the small 'Abd al Kuri, to the west; individuals of this species on the islets of Samha and Darsa, between the two, have been included within the nominate race. Recent studies indicate, however, that *hemileucus* may represent a full species, the "Abdelkuri Sparrow", much paler than the

The ground-sparrows (Pyrgilauda) *differ from snowfinches* (Montifringilla) *in occupying alpine steppe rather than rocky habitats, and in descending to lower levels in the winter. Three of the five species, including the* ***Rufous-necked Ground-sparrow****, are colourful and distinctively patterned. They nest in the abandoned burrows of small rodents, though at least one species, the less colourful* ***White-rumped Ground-sparrow****, can use its bill and large, strong feet to dig its own burrow.*

[Left: *Pyrgilauda ruficollis*, China.

Right: *Pyrgilauda taczanowskii*, China.
Photo: Dong Lei]

*Most sparrow species are gregarious. Even those that are not social breeders gather in flocks for foraging outside the breeding season. Autumn flocks of **Eurasian Tree Sparrows** can include hundreds or even thousands of birds, which gather to feed on fields of grain. In late autumn these flocks may break up, the adults returning to their breeding areas, while the young disperse in search of breeding colonies to join. While some species may forage with congeners and other seed-eating birds, most sparrows gather in large, single-species roosts, in trees, reedbeds and other sheltered sites.*

[*Passer montanus saturatus*, Wusulin, Tainan, Taiwan. Photo: Jao-Shong Fan]

Socotran taxon and sufficiently divergent genetically to warrant such treatment. Further, it has even been suggested that the population on the small islet of Samha might be an additional, small subspecies of the Socotra Sparrow. Clearly, more research on these poorly known sparrow populations is required.

Finally, the Italian Sparrow, already commented upon, presents one of the most intriguing subjects of taxonomic debate. It is worth bearing in mind that it is often considered to be no more than a hybrid form between the House Sparrow and the Spanish Sparrow, although many taxonomists have treated it as a subspecies of one or the other of those two species. Others consider the Italian Sparrow to be sufficiently different from both of them to be accorded the rank of a full species. Although the current view is that it does warrant recognition as a discrete species, opinions differ over whether it is a stabilized hybrid between the House and Spanish Sparrows or whether it evolved independently in north Africa and subsequently spread northwards to Italy, becoming extinct in the north African area of its origin. The latter view is put forward on the grounds that speciation in animals can occur only through geographical isolation, and not by hybridization. Nevertheless, the principle of economy suggests that the hybridization hypothesis is the more plausible, providing the example that "proves the rule". While the origin of the Italian Sparrow remains uncertain, it is most conveniently treated, as is now common practice, as a distinct species on the grounds that the population is now stable, having resulted from events long past.

*Species that breed in colonies are often strongly territorial in the immediate vicinity of the nest. The male **Tibetan Snowfinch**, for example, uses the large white patch on its wing to signal its ownership, both in display-flights and while perched on the ground. These snowfinches begin defending their territories as early as April, though do not begin breeding until June.*

[*Montifringilla henrici*, Qinghai, China. Photo: Axel Gebauer]

Morphological Aspects

The Passeridae are granivores, seed-eaters. Granivory depends on removal of the hard tegument, or testa, from the seed. This requires special structures in the horny palate, the tongue and the lower mandible, with the associated musculature, to manipulate the seed, remove and dispose of the husk, and gain access to the nutrient kernel. In addition, there are associated specialized developments in the alimentary canal for digesting the seed. Granivory has evolved in a number of passerine families, and these families are separated mainly on the basis of differences in the internal structures developed to deal with this food source. The alimentary tract of the Desert Sparrow (*Passer simplex*) is much shorter than that of the other *Passer* sparrows, suggesting that this species takes a proportionately higher amount of insect food than do its congeners.

Old World sparrows differ from the other granivorous passerine families in the possession of a unique skeletal structure in the tongue, the preglossale, which acts to stiffen it. The sparrow holds the seed transversely in the bill and dehusks it by crushing it with the tongue against the horny palate. The Passeridae have a thick, conically shaped bill which tapers to a point; the large nostrils are partly covered by short rictal bristles and also by the

Fighting sparrows cling to one another with their claws while pecking at each other's heads. Such fights can continue until both birds are lying exhausted on the ground. Sparrows are aggressive to one another around the nest, when foraging, and even in defence of the hollows they create while dust-bathing. Females are more aggressive than males, and are particularly aggressive towards their mates at the nest. It has been suggested that much of the quarrelsome behaviour between males is a release mechanism, the result of suppressing aggressive responses to the female in order to maintain the pair-bond. Threat displays by males are similar to courtship displays, though with feathers sleeked rather than ruffled, and without the wing shivering. When threatening, males face their rivals directly, and may stretch their heads upwards and forwards, exposing the bib. The ***Desert Sparrow*** *is a relatively large-bibbed species, the bib extending from the chin to the upper breast. Among the males of the black-bibbed* Passer *sparrows, bib size has been found to be an indicator of status: males with large bibs tend to be dominant. They are less aggressive towards, and receive less aggression from, other males. However, they are more likely to be the targets of aggression from females. One theory is that females are testing whether the male is as tough as his bib suggests he is.*

[*Passer simplex saharae*, Tunisia.
Photos: Jesús Rodríguez-Osorio]

Preening sparrows scratch their heads by the "indirect" method, bringing a leg up over the folded wing, as this ***Southern Rufous Sparrow*** *is demonstrating. Another form of comfort behaviour associated with keeping clean is bill-wiping. A number of sparrow species have been observed to wipe their bills frequently. Sometimes this follows eating messy food, such as over-ripe berries, but it also seems to function as a displacement activity during or after stressful situations. Male House Sparrows* (Passer domesticus)*, for example, bill-wipe between successive treadings of the female while copulating. Birds may go through the motions of wiping the bill without actually touching a surface.*

[*Passer motitensis*, Kamajab, Namibia. Photo: Peter Ryan]

feathers of the forehead. The bill is most robust and blunt in the rock-sparrows and bush-sparrows, tapering more to a fine point in the snowfinches and ground-sparrows. The Passeridae tend to exploit the medium-sized seeds of grasses and small herbs, in general preferring smaller seeds than those taken by the buntings and allies. The true sparrows, those in the genus *Passer*, specialize particularly on the cereal grains developed by man from large-seeded wild grasses; the rock-sparrows show this preference to a lesser degree, but the snowfinches and ground-sparrows that inhabit high altitudes, above the limits of cultivation, barely specialize on such seeds at all. The bill of those species that have been studied in detail is longer in the summer than in the winter, reflecting the variation in diet throughout the year, from softer invertebrates in summer to harder seeds in winter.

This is a comparatively small family, with relatively little difference in size among the 40 species. They range in length from 12 cm to 17·5 cm and in weight generally from 17 g to 40 g, and are thus relatively small birds. The one exception to this is the White-winged Snowfinch, which, although comparable in length, has been recorded as weighing up to 57 g. Females tend to be smaller than males, but there is considerable overlap in size between the sexes.

Structurally, the Passeridae have broad, somewhat blunt wings, which are rather short in the case of the true sparrows. They have ten primaries, but the tenth, outermost, one is much reduced in length and is rotated dorsally, so that it lies under the ninth primary and is obscured by the coverts; in this respect they resemble the Fringillidae, a family in which they were formerly placed. The wing lengths of the snowfinches and ground-sparrows, which are strong fliers and have extensive aerial displays, are proportionately much greater, on average 65% of the overall length; this is relatively long even when compared with the migratory race *bactrianus* of the House Sparrow and the Spanish Sparrows of the race *transcaspicus*, which migrate over the Tien Shan to winter quarters in northern Pakistan and India. The rock-sparrows and bush-sparrows are intermediate, with wing length 60% of the total length, although an exception is provided by the Pale Rock-sparrow, which has a wing length similar to that of the snowfinches and ground-sparrows and, like them, has an elaborate display-flight; it is migratory. The tail is relatively short, characteristically so on the Common Rock-sparrow, and has twelve rectrices.

The legs of the true sparrows, rock-sparrows and bush-sparrows are short, and the tarsus is covered with large scutes at the front. Those of the snowfinches and ground-sparrows are stronger, these being species that run quickly and use the feet for digging for food and for removing soil from the burrows in which they breed.

Whereas, in the case of the rock-sparrows, bush-sparrows, snowfinches and ground-sparrows, the sexes are alike or closely similar, the *Passer* sparrows exhibit two distinct groups in respect of sexual dimorphism. One consists of the monomorphic grey-headed sparrows and the fairly uniform golden sparrows and Chestnut Sparrow, and the other contains the remainder of the genus, in which the male has a well-patterned head and a black bib and the female lacks these characters. The males of the black-bibbed *Passer* species generally show chestnut or tawny-brown on the head, contrasting with the crown and the paler grey or yellowish cheeks; the chestnut colour also appears frequently in the nape and wings. On most species the back is heavily streaked, although this streaking is lacking on the Pegu Sparrow (*Passer flaveolus*), giving rise to its rather prosaic alternative vernacular name of "Plain-backed Sparrow". The rock-sparrows and bush-sparrows are distinguished by the presence of a yellow spot on the throat, although this is inconspicuous on some species and is difficult to see in the field; moreover, it is lacking on one, the rather different and anomalous Pale Rock-sparrow. In contrast to the rather muted colours of the last group, the snowfinches and ground-sparrows are conspicuously plumaged, most species exhibiting varying amounts of white, particularly in flight and, especially, during the display-flights, and many of the males having a small black chin patch.

Plumage abnormalities are not uncommon in this family, primarily among the *Passer* sparrows. Partial replacement of up to 50% of the male's black bib feathers by chestnut ones is fairly frequent, occurring in about 3·5% of individuals. Albinism, both partial and complete, is slightly less common, although it affects 1–2% of the birds. Melanism is found in about 0·2%. Not to be confused with melanism, a darkening of the plumage by soiling is quite common in built-up areas, particularly industrial ones, but more confusing is the appearance of sparrows with a bright yellow head; this is the result of contamination by pollen acquired when the birds are searching the flowerheads for insects. Two House Sparrows with rosy-red plumage were seen in August 2004 in Glenbervie, in Scotland. This was not, however, an example of

Sparrows bathe by standing in water and using their wings to flick water over themselves, while ducking their heads under the surface. In urban areas, ***House Sparrows*** *will bathe in puddles in the street. Bathing is a social activity, and is always followed by preening. Afterwards, the birds may gather in a sheltered place to rest, and indulge in social singing—a conversational babble including softer versions of their social contact calls, in which the whole flock joins. Something similar is heard at communal roosts, where it is less conversational-sounding, and interspersed with threat and alarm calls, as the birds quarrel over favoured perches.*

[*Passer domesticus domesticus*, Öland, Sweden. Photo: Markus Varesvuo]

erythrism, which is very rare in sparrows, but was thought to have been the result of the birds feeding on a food prepared for farmed salmon (*Salmo*), and which was based on ground prawns (Dendrobranchiata), during the period of feather growth after the moult. It certainly is the case that birds in aviaries have been coloured in this way by being fed with special diets containing, for example, paprika and Cayenne pepper, a product of the seeds of *Capsicum*, at the time of the growth of new feathers.

The young of this family are born naked, without natal down. They undergo a complete post-juvenile moult, beginning 1–3 months after fledging, when they become almost indistinguishable in the field from the adults. The adults have a single annual post-breeding moult. For the temperate populations this starts after the rearing of the last brood, and lasts for about 60–70 days. In the tropical and subtropical populations, however, there may be some overlap in the timing of the of moult and breeding, or the moult may be discontinuous, starting during interruptions of breeding, such as for House Sparrows in India during the monsoon, and in these cases it can last for up to 130–150 days. The freshly moulted plumage tends to be somewhat paler than that of the breeding adult, the full breeding plumage being exposed as the pale feather tips are abraded. This is particularly so with the black-bibbed sparrows, the bib increasing both in size and in intensity of blackness as the male comes into breeding condition. Abrasion of the feathers is, of course, one of the reasons for the need to replace them periodically. The appearance of Cape Verde Sparrows (*Passer iagoensis*) nesting in holes in lava cliffs suggests that the parents sustain so much wear through brushing against the rough lava that there is a danger that, by the end of the breeding season, their flying ability will be seriously impaired and a set of replacement feathers is badly needed.

A feature of many species in the family is a seasonal change in the colour of the bill, which is pale brown or horn in the non-breeding season, becoming black on the sexually active male. This is particularly characteristic of the black-bibbed true sparrows, but it occurs also among the monomorphic species. In some, such as the African grey-headed sparrows, it remains black throughout the year in both of the sexes. A similar seasonal colour change is apparent in both sexes for most of the snowfinches and ground-sparrows, but this phenomenon is less marked in the rock-sparrows, most of which retain a horn-coloured bill throughout the year.

The gait of the true sparrows, the rock-sparrows and the bush-sparrows is a hop, although the grey-headed sparrows occasionally walk. Walking and even running are more common methods of locomotion among the snowfinches and ground-sparrows and in the Pale Rock-sparrow, species that live in open, treeless country.

Habitat

It is likely that the family originated in a semi-arid to arid grassland with scattered trees, where the seed-eating habit evolved, although there has been considerable radiation from this habitat. It is still the typical habitat for many of the true sparrows, such as the superspecies based around the Southern Rufous Sparrow (*Passer motitensis*), the rock-sparrows, and the snowfinches and ground-sparrows. Some species, however, have moved into desert or semi-desert, examples being the Desert Sparrow, the Saxaul Sparrow (*Passer ammodendri*) and the two golden sparrows, while others have adopted much more humid areas, as illustrated by, for example, the grey-headed sparrows in Africa and the Spanish Sparrow and Sind Sparrow (*Passer pyrrhonotus*) in the Northern Hemisphere. Some have even penetrated light woodland, as evidenced by the bush-sparrows and the Eurasian Tree Sparrow, but none has become a true woodland species.

The snowfinches and the closely related ground-sparrows are very much birds of high altitudes, the former associated with rocky country and settlements high in the mountains, remaining close to the snow-line throughout the year. The ground-sparrows are associated more with mountain-steppe country, frequently descending to lower altitudes in the winter. The Afghan (*Pyrgilauda theresae*) and Blanford's Ground-sparrows (*Pyrgilauda blanfordi*) occur in dry arid areas, but do not overlap in range. The other three ground-sparrows are found more commonly in damper areas. The Small Ground-sparrow (*Pyrgilauda davidiana*) lives usually close to water on the edges of marshes in semi-desert and rocky plains, and is generally separated by distribution from the Rufous-necked Ground-sparrow (*Pyrgilauda ruficollis*), which is found near small watercourses, and the White-rumped Ground-sparrow (*Pyrgilauda taczanowskii*), which occurs in the drier parts of marshy areas.

Probably the most significant feature of habitat use by this family has been the development of a close association with man,

Sparrows are among the few passerine families which indulge in dust-bathing, as well as bathing in water; the former would presumably have originated in habitats where standing water was scarce. Like water-bathing, it is a social activity, and flocks of over 100 ***Spanish Sparrows*** *have been reported dust-bathing together. The sparrows first scoop out a small depression in dry soil or sand by scratching with the feet and bill. These hollows, which pit the ground in suitable places, are defended vigorously. In a manner similar to water-bathing, dust-bathing involves flicking movements of the wings, to throw dust particles over the feathers. Members of this family use the same motions to bathe in wet or powdery snow.*

[*Passer hispaniolensis hispaniolensis*, Lesvos, Greece. Photo: Gary Thoburn]

initially through feeding in cultivated land on cereal crops, especially where there are hedgerows or trees in which the birds can take cover, and ultimately extending into habitations and built-up areas. This is particularly the case with the true sparrows in the genus *Passer*, no fewer than 17 of the 26 species of which nest on man's buildings, two of them, the House Sparrow and Eurasian Tree Sparrow, becoming predominantly inhabitants of villages and towns; other species use buildings, as well as areas away from man. House Sparrows tend to be the dominant urban species, although the situation becomes less clear-cut in the east of its range. For example, this species and the Eurasian Tree Sparrow nest side by side in the built-up environment in Siberia, Mongolia and Assam, whereas in Afghanistan there is a complete role reversal, with the Eurasian Tree Sparrow in the towns and the House Sparrow only in open, uninhabited country. One other place in which the House Sparrow is not completely dominant in an urban area is Mindelo, on San Vicente, in the Cape Verde Islands, where the indigenous Cape Verde Sparrow is as much at home as the introduced House Sparrow in the centre of the town.

Where House Sparrows are lacking, as, for example, on Sardinia, the Eurasian Tree Sparrow, a recent colonist, is dominant over the Spanish Sparrow as a breeding species in the towns, although in areas where both the House and the Eurasian Tree Sparrows are absent, as, for instance, on Madeira and in the Canary Islands, the Spanish Sparrow moves freely into the towns. The Spanish Sparrow also becomes a village bird in those Saharan oases in which there are no House Sparrows. On the Italian mainland, Italian Sparrows and Eurasian Tree Sparrows share the urban habitat. Similar relationships exist between the House Sparrow and the Russet Sparrow (*Passer rutilans*) in the Himalayas and between the Eurasian Tree Sparrow and the Pegu Sparrow in Thailand, where the House and Eurasian Tree Sparrows are respectively the dominant urban species, with the other relegated to the more open areas on the outskirts.

Away from built-up areas, there is a fairly clear habitat separation. For example, the Spanish, Dead Sea and Sind Sparrows tend to occur in moister areas than those frequented by the more aridity-loving House Sparrow. Again, the African grey-headed sparrows prefer more humid areas than those inhabited by the rufous sparrows, although even within the grey-headed sparrow superspecies there is some separation in the small areas of overlap, with the Parrot-billed Sparrow (*Passer gongonensis*), for example, found in more arid country than Swainson's Sparrow (*Passer swainsonii*).

Less overlap in distribution occurs between species in the rock-sparrow and bush-sparrow complex, but where it does occur there is, again, a separation into the drier areas and the more humid ones. The Pale Rock-sparrow is found in more arid country compared with the Common Rock-sparrow, and the Russet-browed Bush-sparrow (*Gymnoris dentata*) in more arid country than that occupied by the Yellow-spotted Bush-sparrow (*Gymnoris pyrgita*).

Some members of the family have very specific requirements for nesting and roosting. The Dead Sea Sparrow prefers

Many of the calls of the genus Passer *are variants of the basic disyllabic "chirp", and their songs consist of similar notes strung together. The* ***Pale Rock-sparrow*** *is unlike the rest of the family in having a song that recalls those of finches (Fringillidae), consisting of a monotonous, insect-like buzzing, reminiscent of the "wheeze" of a European Greenfinch* (Carduelis chloris). *The song may be given from the top of a rock or bush, although early in the breeding season, unpaired males fly from one songpost to another in a display-flight that may include singing.*

[*Carpospiza brachydactyla*, Isikli, Gaziantep, Turkey. Photo: Emin Yogurtcuoglu]

Snowfinches (Montifringilla) *and ground-sparrows* (Pyrgilauda) *have more elaborate songs than other members of the family. The song of the* ***Black-winged Snowfinch*** *is a distinctive single note repeated rather monotonously from the top of a rock or during a display-flight. Although similar in appearance to the point that they were once considered conspecific, the White-winged Snowfinch* (M. nivalis) *has a very different song, a complex mix of varied buzzy chirps and other calls, with much repetition of individual elements. The flocks of Black-winged Snowfinches which form after breeding keep up a constant soft twittering.*

[*Montifringilla adamsi xerophila*, Tsaring Nor, China. Photo: Axel Gebauer]

dead trees standing in water, the Sind Sparrow seeks trees and bushes beside rivers and marshes, and the ground-sparrows require areas with numerous small-mammal burrows, but most are very adaptable and will use a wide variety of sites. House Sparrows prefer holes for nesting, but in new housing estates with little availability of holes they readily accept thick conifer hedges. The ground-sparrows utilize the burrows of small rodents not only for nesting, but also for roosting and for escaping from predators, each species tending to specialize on a particular mammal.

The extent to which the House Sparrow has exploited the habitat created by man is quite extraordinary. In tropical Latin America, where it has been introduced, it forages on the ground in the early hours, avoiding the heat of the day by resorting to the shade trees that are a feature of the plazas in the towns. At the other extreme, it has been able to spread north of the Arctic Circle in Norway, surviving the cold and continuous dark by moving into the cattle byres, where there was heat, light and food. The act of moving into buildings is not limited to extreme conditions. For example, those introduced in Queensland, in north-east Australia, spend most of the day inside farm buildings, rather than in the open, and could easily be overlooked. House Sparrows also come into covered rail stations, a fact celebrated in Joan Pomfret's poem *Railway Sparrows*:

> "... underneath the station's high arched dome
> A dozen happy sparrows make their home!
> Perhaps they like the bustle and the din.
> The sooty railway air to flutter in –
> The shining rails, the steam, the distant drums,
> The picking of the rail-bar's scattered crumbs,
> And engine smoke ascending, dense and blue,
> The clatter as the Royal Scot comes through."

Further, they readily enter large industrial buildings with easy access, which provide shelter and spilt food scraps from the luncheon packets brought in by the workers. The latest development is that they have learnt how to open the electrically operated doors by interrupting the electronic beam that acts as a switch. This is not just an isolated occurrence, either, as it has been reported from at least four widely separated areas in the last 20 years: from Melbourne and Wagga Wagga, in Australia, from Hamilton, in New Zealand, and from Nantes, in western France. Both House and Eurasian Tree Sparrows have utilized the artificial lighting at airports and other public buildings to enable them to continue feeding their nestlings throughout the night, exploiting the insects attracted to the lights.

The Common Rock-sparrow, too, exhibits some association with humans, coming into the edges of habitations and nesting on buildings. Even the high-altitude snowfinches and ground-sparrows make use of inhabited areas in which to feed, the White-winged Snowfinch particularly at winter ski resorts, where it picks up scraps of food discarded by visitors, and Blanford's and the Rufous-necked Ground-sparrows at rubbish dumps on the edges of villages.

The Passeridae are essentially seed-eaters, specializing in the seeds of grasses, including cultivated cereal crops, and small herbs. Deviations from this basic diet reflect food availability. The ***Yellow-spotted Bush-sparrow****, found in a variety of dry, open habitats with trees, eats the berries of the salt-tolerant toothbrush tree* (Salvadora persica). *Like other members of the family, it forages on the ground, but* Gymnoris *bush-sparrows spend much time in trees, where they search for insects in the manner of tits (Paridae).*

[*Gymnoris pyrgita pyrgita*, Ishaqbini, Tana River, Kenya. Photo: Roland Seitre]

Cultivated grain can make up as much as 75% of the diet of the House (Passer domesticus) *and* ***Spanish Sparrows****, with oats and wheat predominant, and barley, millet, rice and other cereals featuring less regularly. Seeds are taken both from the ripening plants, and from the ground where they have fallen or been spilt. The birds use their weight to pull the heads of taller grasses and cereals down to the ground, where they can be dealt with more easily.*

[*Passer hispaniolensis hispaniolensis*, Lesvos, Greece. Photo: Mathias Schäf]

General Habits

The Passeridae are predominantly gregarious, many species breeding in loose colonies (see Breeding), and even those that are not social breeders gather in flocks for foraging outside the breeding season and form large social roosts. Only one species, the Southern Rufous Sparrow of southern Africa, is by habit a solitary nester, and even outside the breeding season it is seldom seen in anything more than family parties.

Social behaviour is most pronounced outside the breeding season, when large flocks are formed. These forage for seeds on the ground, often not only with congeners but also with other seed-eaters, such as buntings and finches. Unlike the latter groups, the sparrows preferentially forage close to cover, such as bushes and hedges, into which they can flee for protection against predators. Seed-eaters alternate periods of feeding with periods of resting as the seeds are digested. A special feature of the sparrows is a tendency to collect in cover when they are not foraging and to indulge in "social singing", which is characterized by soft conversational chirruping incorporating quiet versions of the social contact and mildly aggressive calls. It is a frequent habit of House Sparrows even in the short winter days of the temperate regions, a fact that suggests that the birds are not having too much difficulty in finding food. This same behaviour has been noted for a number of the species and may be quite widespread, involving some of the less well-studied members of the family.

In contrast to the mixed-species feeding flocks, the sparrows form predominantly single-species roosting associations. These roosts can be very large, often involving many thousands of individuals. For example, R. E. Moreau reported a post-breeding roost in Egypt that contained about 10,000 House Sparrows. In the Mediterranean region, the Spanish Sparrow comes into inhabited areas to roost in the thick shade trees that are present in many of the town squares. These roosts can be very conspicuous, the birds wheeling around in flight before they settle. The numbers of sparrows can be large and can represent a considerable nuisance. For example, in the town of San Antioco, on Sardinia, a roost in the shade trees in the Corso Vittoria Emanuel was estimated to contain several tens of thousands of individuals. This street was closed to traffic at night, and had to be cleaned with mechanical roadsweepers before it could be opened again to traffic in the morning.

For the purposes of roosting, the sparrows use well-covered sites, such as thick bushes and trees, palm crowns, creepers and reedbeds. Although very gregarious, the passerids are not typically close-contact birds, mated partners maintaining their individual distance. The one exception is the Eurasian Tree Sparrow, presumed mated pairs of which can be seen snuggled up one against the other.

The bush-sparrows, while still foraging on the ground for food, spend even more time in the trees, not only for resting, but also for much of their food-gathering. The snowfinches and ground-sparrows are typically ground birds, inhabiting open areas where trees and bushes are absent. They nest in rock crevices or in the holes of small mammals in the ground, some species even spending a lot of time out of sight in the holes, where they

Several species of sparrow will feed on nectar when available, and as with this ***Chestnut-shouldered Bush-sparrow****, their foreheads may acquire a golden dusting of pollen. This can also happen when sparrows are searching flower heads for insects. Having fed on nectar, this bird is now eating small berries. However, despite its comparatively long and slender bill, this species is primarily a seed-eater. Unlike the other three* Gymnoris *species, it spends more time foraging on the ground than in trees.*

[*Gymnoris xanthocollis*, Oman. Photo: Markus Varesvuo]

roost, shelter and take refuge against predators. They use their long bills and strong feet for removing loose soil from the burrows, and one species, the White-rumped Ground-sparrow, is even capable of digging its own burrow.

As the Passeridae are essentially ground birds, the typical gait of all of the species is that of hopping. Nevertheless, walking is utilized frequently by at least one true sparrow, the Southern Grey-headed Sparrow (*Passer diffusus*), and is common for the snowfinches, the ground-sparrows and the Pale Rock-sparrow, which are much more birds of open country with behaviour approaching that of the larks. Many of the *Passer* sparrows, however, when searching for seeds and insects, also indulge in acrobatic behaviour in trees in the manner of tits (Paridae). Some species that live in close association with humans have put this acrobatic facility to good use by hanging on to wire peanut feeders, copying tits and such finches as the European Greenfinch (*Chloris chloris*) and Eurasian Siskin (*Carduelis spinus*), which are particularly well adapted to this feeding technique.

This family is one of the few passerine families that indulges in dust-bathing. Such behaviour is indicative of an origin in an arid habitat, and is one characteristic that differentiates the Old World sparrows from the weavers. In order to dust, the sparrows first scoop out a small depression in dry soil or sand by scratching with the foot and bill-flicking. They are unusual also in that they bathe in water, as well as dusting. The "stand-in" method of water-bathing is used, with a wing-flicking action similar to that employed in dusting. The only other passerine family with the combination of dusting and stand-in bathing is the completely unrelated wrens (Troglodytidae). The passerids perform the same wing action also in both dry and melting snow, which can be interpreted as a combination of dusting and bathing.

Both dusting and bathing are social activities. Up to 20 or more House Sparrows can be seen dusting together, and in favoured places the ground becomes pockmarked with dusting hollows that are vigorously defended against rivals. Both of these maintenance activities are regularly followed by sunning. In this, the bird lies flat in a secure place, as, for example, on a roof, with the wings spread and the body feathers fluffed out, allowing the sun's rays to penetrate. Preening is also regular. During head-scratching the indirect method is used, the bird bringing a leg up over the folded wing.

While not necessarily a family characteristic, one feature of the House Sparrow's behaviour has attracted much attention and therefore deserves special mention. This is the habit of flower-tearing in the spring, yellow flowers being particularly affected. No completely satisfactory explanation of the behaviour has been put forward, leading to its having been described as being purposeless and mischievous. This seems inherently improbable, and it appears more likely that, even if the petals appear to be merely torn and scattered, the sparrows are also obtaining some sustenance. It may be relevant that the behaviour is more frequent in dry springs with little rainfall.

Voice

The chirping call of the House Sparrow is so characteristic of the more familiar members of the genus *Passer* that the epithet "sparrow-like" is frequently used in descriptions of the calls of other passerine species. The main call of the House Sparrow is a basic monosyllabic "chirp" or disyllabic "chirrup", which has given the bird the colloquial name of "Philip Sparrow": in the words of one author, "all sparrows are called Philip, 'phip phip' they cry". This call, with variants, is common to all members of the genus *Passer*. It is the primary call used in contact situations with conspecifics and at the nest. The females use a similar, though softer version. Again, in appeasement contacts between partners and between the pair and its young, the harsh chirp is transformed into a soft "chee", "quee" or "dee", which is used as an invitation to coition or by the young in begging for food. An even softer version of this same call is used as a greeting at the nest by members of a pair.

A further circumstance in which the basic chirping call is prominent is what is best described as "social singing". This occurs when a group of sparrows is resting together in cover, with the notes much softer and more conversational in character than the similar calls used in advertising situations. The conversational nature of social song is illustrated also by the way in which the whole sound ebbs and flows as different numbers of individuals join in.

The basic chirp is used by the male to proclaim ownership of a nest, and the notes can be strung together as a series to form a rudimentary song, which is used by the unmated male to attract a mate. In the case of the highly social Spanish Sparrow, this song can be represented as a strident, repeated "chweeng-chweeng" or "cheela-cheela" uttered in pairs, higher-pitched and louder than that of the House Sparrow, to the extent that it can be heard at a

*Found in truly arid areas, the **Desert Sparrow** obtains most, if not all, of its water requirements from its food. This species feeds on the "acheb" flora, short-lived grasses, mustards (Cruciferae) and other vegetation that springs up after seasonal rain. Its primary food is the seeds of permanent grasses and other ground vegetation. It seems to eat a higher proportion of animal (insect) food than its congeners, and its alimentary tract is shorter than that of any other member of the family.*

[*Passer simplex saharae*, Tunisia.
Photo: Jesús Rodríguez-Osorio]

In the high-altitude steppe, and the rocky slopes between the tree-line and the snow-line, where the ***Tibetan Snowfinch*** *lives, the seeds of grasses can be in short supply. Little is known about the feeding choices of this species, but studies of its congener, the White-winged Snowfinch* (Montifringilla nivalis)*, in Switzerland, suggest that it actually prefers the seeds of alpine plants to those of grasses growing at lower altitudes. As well as foraging on the ground, the three species in this genus also catch insects in flight. Their remoteness from settlements means they are less associated with humans than the* Passer *sparrows. But with the spread of ski resorts in Europe, the White-winged Snowfinch is commonly seen scavenging for food scraps in the winter.*

[*Montifringilla henrici*, Qinghai, China. Photo: Axel Gebauer]

distance of several hundred metres. Similarly, the basic "chitta" call of the Sudan Golden Sparrow is repeated urgently by the male at the nest, creating a tremendous din in a large colony. Once again, the same applies to the "chip-chip-chip" or "chip-chip-chizza" calling of the Dead Sea Sparrow. All these calling situations are associated with conspicuous wing-shivering. Similar songs and behaviour, although perhaps less noisy and striking, are a characteristic of most, if not all, species in the genus *Passer*.

As is to be expected with highly social species that form flocks outside the breeding season, if not actually breeding colonially, the true sparrows have an extensive range of vocalizations that are used in interactive situations. A further range of calls has a more nasal "quer" sound. There is a gradual transition from this call, which can be given as a single or repeated series of notes or variants such as a nasal "quer-tit", "ki-quer" or "ki-quer-tit" that are used in alarm, to a harsher and more guttural trilled "churr", used as a threat against conspecifics or other intruders at the nest. The alarm calls also serve a social function, alerting other members of a flock, and even different species in a mixed flock, to danger. The Eurasian Tree Sparrow is even said not to call in

Insects and other animal foods can make up to 10% of the diet of ***House Sparrows*** *in the summer. The bills of this and other species are longer in summer than winter, reflecting this change to softer food. House Sparrows forage for arthropods on the ground, but also catch butterflies in flight, and will take dragonflies when these are resting in a semi-torpid state in the cool of the morning. Adaptable and opportunistic, House Sparrows exploit the moths and craneflies attracted to bright lights at night, and pick the bodies of dead insects from the radiators of cars. They will also eat molluscs, small frogs, and in coastal areas, small crustaceans.*

[*Passer domesticus domesticus*, Bulgaria. Photo: Konrad Wothe]

such situations, relying on the calls of other species to give warning of danger.

The Common Rock-sparrow has an even greater range of vocal utterances, generally similar in character to those of the true sparrows and even more varied, although the significance of the different calls and the situations in which they are used have not been studied in detail. The bush-sparrows have a more melodious song, which they deliver from a perch in a tree; their calls are said to be generally similar to those of *Passer* sparrows. In contrast, the Pale Rock-sparrow, again emphasizing its anomalous position, has quite a different, rather finch-like song that is given from a prominent perch on a rock or the top of a bush, the sexes at times duetting. Its calls are more akin to those of *Passer*, but have not been described in detail.

Snowfinches and ground-sparrows have more elaborate songs than the songs of other members of the family. They are delivered from a prominent perch or in display-flights. Unfortunately, their calls, and the contexts in which they are uttered, have not been analysed in the same detail as have those of the *Passer* sparrows.

Food and Feeding

Detailed studies have been carried out on the diets of four species of *Passer*, the House, Spanish, Sudan Golden and Eurasian Tree Sparrows, on the Common Rock-sparrow and on the White-winged Snowfinch, both by analysis of crop and stomach contents, and by the use of neck collars on nestlings. Limited information is available on the diets of the other species, and that mainly from casual observations, although the little that is known suggests that the types of food taken are broadly similar, the variations reflecting availability, rather than pronounced differences in food preferences. Specialization on different types of food can be seen in areas where two or more passerids occur sympatrically, the diet spectrum broadening in areas where there is no overlap and competition is reduced. For the less well-researched species, however, information of this kind is mostly lacking.

All members of the family are basically seed-eaters, specializing on the seeds of grasses, the cultivated cereals derived from them, and small herbs. Many of the data originate from areas in which the birds are, or have been, perceived as pests of arable crops (see Relationship with Man). The nestlings of all of the species are reared predominantly on animal food, consisting of insects and other invertebrates, particularly the larval forms. In the case of the House Sparrow, this is essential for the first three days of life if the young are to survive, although an increasing proportion of vegetable matter is fed to the chicks towards the end of the nestling period. At this time the adults themselves also consume some animal food, the proportion of which and the period of the year in which it is taken varying greatly among the different species and varying also in different parts of the range of those species with extensive distributions. This makes it difficult to make an economic judgement, as many of the insects taken by sparrows are themselves pests of agriculture. The digestive tract of the Desert Sparrow is shorter than that of other species in this family (see Morphological Aspects), and it is suggested that it takes a higher proportion of animal food than the House and Saxaul Sparrows, with which it overlaps in different parts of its range.

Stomach-content analyses have revealed that cultivated grain can make up to 75% of the diet of the House and Spanish Sparrows, with oats and wheat predominant, and barley, millet, rice and other cereals featuring less regularly. The Sudan Golden Sparrow, one of the smallest sparrows, feeds on small millet and rice, but the latter only after it has been dehusked. The balance of the vegetable diet is made up of the seeds of grasses and small herbs, and these are the preferred foods of the Eurasian Tree Sparrow, although rice and millet, and even the larger wheat grains, are also taken. Cereal grains on the plant in the early "milk" stage, when the grains are still soft and contain a milky white fluid, not only are taken by the adults, but also are fed to the older nestlings.

Rock-sparrows likewise eat some cereal grains, but, as they have much less contact with cultivation than true sparrows, they feed predominantly on the seeds of grasses and small herbs. The Common Rock-sparrow forages mostly on the ground, where, having a stouter bill, it tends to take larger seeds than those consumed by the true sparrows. The bush-sparrows are much more arboreal than the other members of the family and, while they will forage on the ground in the manner of the true sparrows, they obtain a lot of their food in the trees, examining the leaves in tit-like fashion and, in particular, using the finer bill to search under the bark for insects. The snowfinches and ground-sparrows

Sudan Golden (Passer luteus) *and* ***Arabian Golden Sparrows*** *are highly gregarious, and outside the breeding season forage in flocks that can include thousands of birds. Foraging flocks progress by "roller feeding", in which the birds at the back continually overfly those at the front. The smallest species in the family, they take correspondingly smaller seeds, such as millet and sorghum. They are considered a serious agricultural pest because of the sheer number of birds that may descend on a cereal crop, but they also help by taking the seeds of weeds from ploughed ground. In one study of stomach contents throughout the year, weed seeds made up 55% of the diet, and cereal grains 30%.*

[*Passer euchlorus*, near Al Dohi, Tihama plain, Yemen. Photo: Peter Ryan]

Although less dependent on humans than most other Passer *sparrows, the* ***Dead Sea Sparrow****, shown here on the left, with a female House Sparrow* (P. domesticus)*, has benefited from man-modified landscapes. Until the 1950s, this species occurred mainly in river- and lake-side habitats, surrounded by semi-desert, where a flush of annual grasses following the winter rains provided a good supply of seeds. The increase of irrigated agriculture in semi-deserts has allowed the Dead Sea Sparrow to extend its range. Its diet also includes the seeds of plants growing in and around water, such as papyrus* (Cyperus papyrus).

[*Passer moabiticus moabiticus*, Israel. Photo: Markus Varesvuo]

that inhabit areas above the level of cultivation feed mainly on the seeds of alpine plants.

Sparrows living in urban areas, especially the House, Eurasian Tree, Italian and Spanish Sparrows, but also some of the other species that penetrate inhabited areas, including the Common Rock-sparrow, the White-winged Snowfinch and some of the ground-sparrows, take food scraps provided by humans, such as bread, cooked vegetables, and meat fibres. Even so, they still prefer seeds and cereal grains if these are available. With the increasing number of Eurasian Sparrowhawks (*Accipiter nisus*) in urban habitats, it is very noticeable that the behaviour of these birds, particularly that of the House Sparrow, has changed. Where they formerly stayed in the open in places where food is available, they now tend to remain in cover, making quick sorties to snatch some food and then retreating back to the cover in order to eat it. In Asia, both the House Sparrow and the Eurasian Tree Sparrow come into the open-fronted shops to plunder any available food. Feed put out for chickens, pigs and other domestic animals is also exploited. In addition, a wide range of vegetable matter is taken opportunistically by all members of the family. This includes buds, green shoots, flowers, tree seeds, a variety of soft fruits, and nectar from flowers; the last has given rise to frequent reports of birds with yellow staining on the breast and forehead, at times even to the extent of making identification of the species difficult. The Cape Sparrow (*Passer melanurus*) has become a pest of viniculture in some areas of South Africa, where

Among the species that have exploited urban environments most successfully, scraps from cooked meals are a regular food source. However, the ***House Sparrow*** *and the Eurasian Tree Sparrow* (Passer montanus) *both prefer seeds when they can get them. Famously bold and confiding with humans, House Sparrows are changing their behaviour in places where Eurasian Sparrowhawks* (Accipiter nisus) *are on the increase. Instead of remaining fully in the open, they make quick sorties to snatch food, which they carry back into cover to eat. This parallels their behaviour in agricultural fields, where they tend to feed at the edges, within a few metres of the cover of hedges or grassy banks.*

[*Passer domesticus domesticus*, Germany. Photo: Roland Seitre]

Although found in semi-arid regions with annual rainfall of less than 750 mm, the ***Cape Sparrow*** *needs to drink regularly, and is seldom found far from a water source. Most members of this family are dependent on water for drinking. Species occurring in semi-arid habitats tend to be found near natural watercourses, or make use of irrigation channels and fish ponds. If water is not available in its feeding and breeding areas, the Saxaul Sparrow* (Passer ammodendri)*, for example, will fly considerable distances several times a day to drink.*

[*Passer melanurus damarensis*, Kgaligadi Transfrontier Park, South Africa. Photo: Geoff McIlleron]

it feeds on the ripening grapes; it is thought that the sparrows were first attracted to the weeds that grew between the irrigated vines, and from there moved on to the grapes themselves.

The range of animal foods is just as wide. Soft-bodied insects, caterpillars, grubs and aphids (Aphidoidea), or larger insects with the hard parts removed, are given to the very young nestlings. Later, more chitinous invertebrates such as spiders (Araneae), beetles (Coleoptera), particularly weevils (Curculionidae), and grasshoppers and crickets (Orthoptera) seem to be favoured, although cranefly larvae (Tipulidae) are preferred by the snowfinches, but any slow-moving invertebrate that is locally plentiful will also be taken by the members of this family. During the breeding season, this animal food is consumed by the adults, as well as being fed to the young. In addition to invertebrates, small amphibians and reptiles are regularly reported in the diets of the Passeridae, and small lizards seem to be a particular speciality of the Italian Sparrow. The House Sparrow is virtually omnivorous, even taking small molluscs and crustaceans along the shoreline.

Seeds are taken both from the ripening plants and from the ground where they have fallen or been spilt. In addition, undigested seeds are taken from animal droppings. In the case of cereals and the larger grasses, the sparrow will fly up from the ground and pull the seedhead down to ground level, frequently breaking the stalks. Many species employ the technique of "roller feeding", in which the individuals at the rear of the flock continually overfly those at the front, so that the whole flock progresses in one direction.

The Passeridae obtain invertebrates by searching on the ground and among the leaves of trees, or by hovering in front of vegetation. They also systematically search the boles of trees. They catch larger insects by pouncing, either from a perch or after hovering low above the ground; larger prey items are caught particularly in the early morning, when they are still torpid. In addition, sparrows catch insects in flight. It is mainly ants (Formicidae) and termites (Isoptera) in the flying stage that they capture in the air, although they seize larger insects, too; for example, they catch bees (Apoidea) coming out of a nest and snap up butterflies (Lepidoptera) in flight, although they are much clumsier than the Old World flycatchers (Muscicapidae) in this technique and may have to make long chases before successfully catching a butterfly. A particular example of exploitation, adopted by several of the passerid species that live close to man, concerns the catching of insects around bright lights at night or the collecting of dead or dying ones on the ground below. This behaviour makes it possible for the adults to feed nestlings right through the night at such places as airports. Sparrows also collect dead insects from motorcar radiators and from the fronts of railway locomotives. Moreover, the ground-sparrows, possessing a stronger bill, will dig into the soil in search of invertebrate prey.

Several studies, mainly of captive sparrows, suggest that the birds require an average of 150–250 kJ per day throughout the year. This translates into about 2–6 g of seed per day, depending on the calorific value of the seeds in question. Feeding bouts are interspersed with periods of rest, during which the seeds are digested. During these rest periods, the true sparrows resort to thick

At the beginning of the breeding season, the unpaired male ***Spanish Sparrow*** *either takes over an old nest, or lays the foundation of a new one. He advertises this site with a "song" consisting of rapidly repeated chirps, "cheeli-cheeli-cheeli". Louder than the song of the House Sparrow* (Passer domesticus)*, this can be heard from several hundred metres away. In the accompanying display, very like that of other* Passer *sparrows, he droops and shivers his wings, spreads and raises his tail, and raises his head to expose his black bib. If he attempts to mate before the female is ready, she rejects him aggressively.*

[*Passer hispaniolensis hispaniolensis*, Bulgaria. Photo: Konrad Wothe]

cover, where they frequently indulge in bursts of social singing (see Voice).

The members of this family regularly drink when water is available, but some of those living in the more arid regions appear to obtain most of their water from the food that they eat. Grit is also taken regularly by sparrows, and is retained in the stomach as an aid to grinding up food. The amount retained varies, from a mean of 210 mg in the House Sparrow, with as many as 3,000 separate particles, to 175 mg in the Eurasian Tree Sparrow. Data of this nature are, of course, not available for the great majority of the passerid species. The choice of grit is not random. House Sparrows, for example, show a preference for angular particles about 0·5 mm in size, and hold on average more grit in the gizzard when they are feeding on hard seeds than when taking softer animal food. Females also take snail shells as a calcium supplement during the egg-laying period.

This photograph is part of a sequence showing previously undocumented and so far unexplained behaviour, in which a pair of ***House Sparrows*** *each held objects in their bills during copulation. The male was perched on the swallow's nest carrying a white feather when the female arrived, holding a petal of Spanish Lavender* (Lavandula stoechas). *During the six or seven bouts of copulation that took place over the next three minutes, the male dropped the feather, but the female kept hold of the petal.*

[*Passer domesticus domesticus*, Monfragüe National Park, Extremadura, Spain. Photo: Nicole Bouglouan]

Breeding

The Passeridae are essentially monogamous, and colour-ringing has shown that, for the sedentary populations of House Sparrows and Eurasian Tree Sparrows, the mated partners normally remain together for life. For these relatively short-lived species, this rarely extends beyond two breeding seasons, although one pair of House Sparrows has been recorded as breeding in the same nest for six consecutive seasons, rearing two or three broods each year. Apart from a brief period at the end of the breeding season when the birds may move away a few kilometres to exploit a ripening grain field, the nest is held throughout the year, often being used for roosting by at least one of the pair, and is defended against rivals. The nest may, in fact, provide a focus for the pair, but away from it the partners obviously recognize each other and spend much time together. Nest-site ownership is clearly not so strong among the other species in the family, and the extent to which partners of these species remain together throughout the year is not known.

In the case of the sedentary sparrows, an unmated male takes over a nest-site at the beginning of the breeding season and adds nesting material, showing ownership by advertisement-calling. On the appearance of a female, the calling speeds up and becomes more strident; this is particularly the case with the Spanish Sparrow, which can be heard at a distance of several hundred metres. If the female is interested, the pair quickly becomes established. Once the pair has been formed, both members carry on with the building of the nest, which may be completed some weeks before egg-laying begins. In the event of the loss of one of the partners at this stage, the remaining sparrow, be it male or female, continues to hold the nest and quickly attracts a new mate. This mate-replacement phenomenon continues throughout the breeding season, suggesting that there is a population of "floaters" that have up to then been unable to join the breeding population. With these sedentary species, there is a recrudescence of sexual activity after the moult, and a bird that disappears is quickly replaced, some birds of the year becoming nest-holders at this time.

The majority of the species in this family breed generally in loose colonies, but at times with the nests closely packed and touching one another. This is evident with, for example, Eurasian Tree Sparrows nesting in the base of large nests of storks

Most sparrows nest in colonies, but two of the species forming the rufous-sparrow superspecies, the Southern Rufous (Passer motitensis) *and* ***Kenya Rufous Sparrows****, are solitary nesters. The Kenyan species is also one of few that place the nest openly in the branches of trees rather than in a hole or another concealed site, although it has been known to build in more sheltered sites, behind creepers or in deserted weaver (Ploceidae) nests. As in the rest of the Passeridae, both sexes build the nest, which in this species is a loose, domed structure the size and shape of a rugby ball, made mainly of grass.*

[*Passer rufocinctus*, Lake Naivasha, Kenya. Photo: Neil Bowman/FLPA]

*The untidy globular nests of **Chestnut Sparrows** are sometimes built in single-species colonies, but may also be situated in colonies of weavers (Ploceidae). Instead of building its own nest, the Chestnut Sparrow may take over an abandoned weaver nest, or eject the weavers from an occupied nest, and some Chestnut Sparrow colonies consist entirely of nests from which weavers have been displaced. The male gives his ownership display from the weaver's nest, sometimes while it is still occupied, attracting a female, and she helps him drive out the weavers. It has been suggested that this species is evolving from a "normal" breeder to a nest parasite.*

(Ciconiidae) or birds of prey, and with tree-nesting Spanish Sparrows. The nests of Sudan Golden Sparrows in the branches of trees may also be close together, but not so close as to be in contact. When nests are very close together, the stealing of nest material is common and there is much agonistic behaviour; neighbouring individuals appear to recognize each other, although still attacking unfamiliar birds. Among those true sparrows that breed in loose colonies, and the Common Rock-sparrow, the bush-sparrows, the snowfinches and the ground-sparrows, the pairs are strongly territorial so far as the nest is concerned, but they join into flocks outside the breeding season.

Colonial breeding is most highly developed in the Sudan Golden and Spanish Sparrows. Colonies of the former containing up to 65,000 pairs have been reported from Senegal. The nests are built in thorny trees, with 20–30 nests in one tree; in the arid region where the birds breed, trees tend to be scattered so that the colony is not closely packed, although 570 nests/ha have been counted in Niger. The Spanish Sparrow is even more gregarious, particularly in the eastern parts of its range, where breeding colonies contain from 100,000 to as many as 800,000 pairs, and an estimated 2,500,000 birds of this species nest in one square kilometre. This means not only that the largest colony is twelve times greater than that of the Sudan Golden Sparrow, but also that the nests are much more densely packed. Whereas the nests of the Sudan Golden Sparrow are spaced and there is much agonistic behaviour between neighbouring pairs and much stealing of nest material, those of the Spanish Sparrow are at times so close together that they form a continuous mass. Up to 180 Spanish Sparrow nests have been counted in one tree in Spain, and as many as 20 in the base of a single nest of a European White Stork (*Ciconia ciconia*).

Even with the Sudan Golden and Spanish Sparrows, the above-mentioned figures represent the extremes, and much smaller and looser colonies also occur. This is the tendency too for most of the other true sparrows, 20–30 pairs being far more typical for such species as the House Sparrow, Eurasian Tree Sparrow, Dead Sea Sparrow, Sind Sparrow and Cape Verde Sparrow, among others. The breeding associations form a clumped distribution even in areas apparently offering equal nesting opportunities, so that the birds can thus be fairly described as colonial breeders by choice, rather than as a result of habitat restriction. This is borne out by the current decline of the House Sparrow population nesting in urban areas in Britain (see Status and Conservation). As numbers have fallen, the "colonies" have maintained their average size, but the nests have become more widely spaced, the birds withdrawing from areas which were formerly suitable for breeding and which do not appear to have changed in this respect.

The rock-sparrows and the snowfinches tend to nest in similar loose colonies, although, with the hole-nesting species, the structure and spacing of the colony depends more on suitable nesting opportunities than is the case with the tree-nesting species. The ground-sparrows, however, are more territorial, although they do associate in flocks outside the breeding season.

Solitary nesting also is practised by many of the Passeridae, but only for one, the Southern Rufous Sparrow of southern Africa, is this the rule. Nests of this species are rarely, if ever, less than one kilometre apart, and even outside the breeding season this sparrow is seldom seen in flocks other than single family parties.

Breeding is linked with the normal succession of the seasons in temperate regions, but for those species living in the tropics it tends to coincide with the local rains, perhaps giving rise to separate breeding attempts at different times of the year. Synchronization of breeding occurs in the colonial species, resulting in peaks in the timing of laying of the clutches, although this becomes less marked as the season progresses, replacement clutches tending to disrupt the cycle.

For nesting, the majority of the members of the family use covered sites, especially holes in trees, cliffs and buildings, but they nest also in creepers and more openly in the branches of trees. The nests are usually domed, and this is true even of those built in more open sites in trees, in which they are securely interwoven with the branches. Passerid nests are normally constructed from dried grass and plant stems, and lined with a soft pad of

In the absence of competition from House Sparrows (Passer domesticus), ***Spanish Sparrows*** *will nest on buildings, but otherwise they tend to choose natural sites, including trees, and the nests of larger birds such as raptors, crows and storks. The loose grass of the nests of a sizeable colony can be seen spilling out from this European White Stork* (Ciconia ciconia) *nest. Spanish Sparrows tolerate much closer proximity of nests within their colonies than most other sparrow species. The nests here are packed so closely together that the material has become intermingled. Up to 20 pairs of Spanish Sparrows have been found in a single stork's nest, and in Spain, 180 nests were counted in one tree. In the east of its range, colonies can contain from 100,000 to as many as 800,000 pairs.*

[*Passer hispaniolensis hispaniolensis*, Lake Kerkini, Greece. Photo: Manfred Pfefferle]

hair, fur or feathers. The snowfinches nest in crevices in rocks and under boulders, whereas the ground-sparrows use almost exclusively the burrows of small mammals, normally the only covered site in the sparsely vegetated high-altitude steppe habitat in which they live. Even when covered sites are used, the nest is usually still domed, although it may be reduced to a mere pad in the case of some of the bush-sparrows and rock-sparrows, the snowfinches and the ground-sparrows. The Chestnut Sparrow of tropical Africa not only builds a nest openly in the branches of trees, but is also a nest parasite, usurping the nests of a number of ploceid weaver species. Similarly, the House Sparrow will sometimes take over the nest of another species, such as that of a Northern House Martin (*Delichon urbicum*), and this versatile species has also been recorded as living and breeding 640 m below ground in a coal mine in South Yorkshire, in England. The one striking exception within the family is the Pale Rock-sparrow, which builds an open cup-nest in a bush, more like that of a finch than like the typical nest of a sparrow.

The clutch size is typically of three to five eggs. In the case of the true sparrows in the genus *Passer*, both sexes take part in incubation, although the males, as they do not develop a brood patch, can be said only to cover the eggs, rather than truly incubate them. With the population of the Dead Sea Sparrow nesting in the Dead Sea Depression, the ambient temperature during the day is such that incubation is not required. Here, the female even prevents the male from entering the nest during this period, although in areas with less high temperatures pair members behave more normally. Similarly, there may be no need for incubation during the day for Desert Sparrows living in hot regions, and true incubation takes place only at night. Both the Dead Sea Sparrow and the Sudan Golden Sparrow, the latter living in the high-temperature tropics, build open-structured nests of small twigs, rather than of grass, which shelter the eggs from the direct heat of the sun and at the same time allow circulation of cooling air that prevents overheating of the clutch.

Incubation periods of the Passeridae are typically 12–14 days, but that of the Sudan Golden Sparrow, which has adapted to a short window in which the local conditions may be suitable for successful breeding, lasts for only 10–12 days. In all of the species for which relevant information is available, both sexes bring food for the nestlings and both continue to feed the young for up to two weeks after they leave the nest. If the female lays a new clutch, however, most fledgling feeding is done by the male. The fledging period for most of the species is typically 14–17 days, although, again, the Sudan Golden Sparrow is the exception, with a fledging period of only 13–14 days. The window of opportunity for breeding in the Sahel, where the Sudan Golden Sparrow occurs, can be very short. This results not only in a high degree of synchronization, but also in a breeding cycle that is shorter by five or six days than that of other sparrow species. With suitable conditions of such comparatively brief duration, the birds, having bred once, may then move to another location for a further breeding attempt, those pairs that started late in the cycle deserting their nests and moving on with the flock. The Spanish Sparrow is another species for which, in certain parts of its range, conditions suitable for breeding may be of limited duration. This sparrow is adapted to breeding in areas with a Mediterranean-type climate where there is a short flush of vegetational growth, with an associated flush of insects, before a long hot, dry summer sets in. Some populations of Spanish Sparrows accommodate to this by moving for successive broods to areas in which the conditions become suitable later in the year (see Movements).

In contrast, the White-winged Snowfinch has a longer fledging period, amounting to 18–22 days, suggesting a limited availability of food for the young. This may be typical of the other high-altitude snowfinches and ground-sparrows, but data for these species are lacking.

Since the complete breeding cycle takes only four to six weeks, there is ample opportunity for several broods to be raised in most areas. The majority of the species lay two to four clutches, and as many as six breeding attempts by House Sparrows have been recorded in India, although breeding can be interrupted during the monsoon, the birds then taking the opportunity to begin the moult when conditions are not suitable for breeding.

Hole-nesting species make use of a wide variety of natural and man-made sites. The highly social ***Common Rock-sparrow*** *breeds mainly in loose colonies of up to 100 pairs. Its nests are placed in crevices in rocks, rodent burrows or the nesting tunnels of birds such as bee-eaters (Meropidae) or Collared Sand Martins* (Riparia riparia). *They also make use of holes in ruined or isolated buildings, and occasionally in occupied buildings. The nest material, grass lined with feathers and animal hair, fills the space available. The nests are often domed, like those of the genus* Passer. *Spacing depends on the availability of holes, but at times Common Rock-sparrow nests may be only a few metres apart. The* ***Desert Sparrow*** *nests alone or in small colonies. In Africa this species most often nests in holes in trees and deserted buildings. Elsewhere, it sometimes builds nests in open sites, such as the dense branches of thorny trees and the crowns of palms. The nests are tightly interwoven with the branches of the tree. Built of plant fibres and coarse grass, they are domed, with a side entrance sloping up to a nest cup of finer grass, fibres and feathers. Nests may also be found in the understoreys of large crow or raptor nests. Both partners work on the nest, and continue to add material until the first young hatch. In hotter parts of the range, these birds may not need to incubate the eggs during the day, and sites such as the bases of large nests of other species may be favoured because they shelter the eggs from the direct heat of the sun, which could overheat them.*

Despite the apparent faithfulness of paired individuals of the House Sparrow that is suggested by close observation of colour-ringed birds, DNA studies have revealed that there is a considerable degree of promiscuity. Indeed, it has been found that a significant percentage of eggs in a nest have not been fertilized by the male nest-owner. This is particularly evident in colonies where the nests are close together, and in such colonies some females may even lay in neighbouring nests. This is not a case of nest parasitism; rather, the female mates with the owner of the neighbouring nest, presumably as a means of increasing the probability of ensuring the propagation of her own genes. Intriguingly, these molecular-genetic studies have shown that 10–20% of nestlings have not been fathered by the male partner of the pair feeding the young, a figure remarkably similar to the reported rate for the human population living in apartment blocks in England.

Data on breeding success are available for only a few well-researched species, such as the House Sparrow and the Eurasian Tree Sparrow. The figures exhibit an extremely wide scatter, the values for the percentage of eggs laid giving rise to fledged young ranging from 30% to 95% in different studies. Published data suggest only a 30% breeding success for the Desert and Dead Sea Sparrows, although it is not known whether this low value is typical for these species or is merely a reflection of the fact that it is derived from very restricted studies and is not truly representative of the species concerned. Studies of the widespread House and Eurasian Tree Sparrows suggest an annual productivity of 3–10 fledged young per pair per year. Again, data on life expectation appear to be limited to these species. As might be predicted for a small passerine, the life expectancy of the adults is short, less than two years, although ringing recoveries have shown that individual Eurasian Tree Sparrows have lived for four years, Spanish Sparrows for eight years and House Sparrows for an astonishing 13 years in the wild. It is perhaps not surprising that these three are among the most successful of the sparrows, with a track record of successful colonization.

Movements

Although the Passeridae include some of the most sedentary of all wild birds outside the tropical forests, most of its members do make movements of some kind. These range from a truly directed seasonal movement undertaken by some species, or at least by some populations, to the nomadism exhibited by some tropical species and to a post-breeding dispersal, particularly of juveniles, or local movements involving flights of only a few kilometres to reach a seasonal food source. At the other extreme, many House Sparrows, for example, live out their whole life within a compass of no more than one or two kilometres.

The subspecies *cinnamomeus* of the Russet Sparrow and the subspecies *parkini* of the House Sparrow, breeding at high altitudes in the Himalayas, have a regular vertical migration to lower altitudes. In the case of the Russet Sparrow, for example, this may involve a descent of 2–3 km, but with a lateral displacement of only 10–25 km. In contrast, the nominate race of the Russet Sparrow, which breeds on the island of Sakhalin, in much of Japan, and in northern China, withdraws completely to the south, to spend the winter months well away from the breeding area. House Sparrows and Eurasian Tree Sparrows living at high latitudes in Siberia either shift south or move into built-up areas in the winter. The race of the House Sparrow, *bactrianus*, that breeds in southern Siberia, the Central Asian republics and Afghanistan is a summer visitor in those areas, wintering in the plains in the north of the Indian Peninsula.

As already indicated (see Breeding), Spanish Sparrows have a rather different type of migratory behaviour. They carry out extremely complex seasonal movements in north-west Africa, searching for suitable breeding areas in response to annual variations in rainfall, whereas, to the east, movements appear to be more directed, the sparrows moving northwards for successive breeding attempts in order to take advantage of the flush of food that coincides with the advancing Mediterranean-type spring as conditions become progressively more favourable towards the north and east. This migration reaches as far as Kazakhstan, southern Siberia and extreme north-west China. It results in a spectacular autumn passage as the birds return south through the passes of the Tien Shan to the northern plains of India, where they spend the winter.

Like the Spanish Sparrow in north-west Africa, the Sudan Golden Sparrow of the Sahel region, farther south in Africa, is nomadic. This sparrows follows the rains, breeding in enormous concentrations when there is a flush of vegetation, with the attendant insects on which it relies for the rearing of its young.

The ground-sparrows not only breed but also roost and shelter in the burrows of rodents. These are often the only sheltered sites in the sparsely vegetated regions of high-altitude steppe where they live. Each species tends to be associated with one or more species of small mammal. ***Blanford's Ground-sparrow****, for example, nests mainly in the burrows of pikas* (Ochotona) *or Brandt's voles* (Microtus brandti), *and Small Ground-sparrows* (Pyrgilauda davidiana) *in those of susliks* (Citellus), *pikas and hamsters* (Cricetus). *The nest may be up to a metre from the entrance to the burrow, and consists of a mat of grass and other plant material, lined with fine vegetable fibres and animal hair.*

[*Pyrgilauda blanfordi*, China. Photo: Axel Gebauer]

In the Passer *sparrows, both parents incubate the eggs. This is thought probably to be the case too with the* ***Black-winged Snowfinch****, although in the closely related White-winged Snowfinch* (Montifringilla nivalis)*, the female alone appears to incubate. In all species for which the information is available, both parents bring food for the nestlings; this is certainly true for the Black-winged Snowfinch. Clutch sizes in this family are within the range 3–5, and the eggs are incubated for 12–14 days.*

[*Montifringilla adamsi*, China.

A much more limited movement, but nonetheless a regular one, occurs among otherwise sedentary populations of House Sparrows living in villages and on the outskirts of towns. These birds will abandon their breeding colonies and take up temporary residence in the surrounding countryside a few kilometres away, where they take advantage of the availability of the ripening grain, returning to the colony areas once the grain has been harvested.

Post-breeding dispersal is a much more significant feature of the *Passer* species than any true migration, and the distances involved may be quite limited. This is the mechanism whereby gaps in the breeding population are filled, and new colonies become established in suitable areas. It is also the one by which the remarkable colonizations of birds introduced in new areas have certainly taken place. At the beginning of the nineteenth century, the House Sparrow in the Palearctic Region extended as far east only as the Urals, yet with the exploitation of Siberia for agriculture, and the building of the Trans-Siberian Railway, it had, by the 1920s, spead to the mouth of the River Amur, on the Sea of Okhotsk, an extension of range of some 5000 km in a little over 100 years. Similar range expansions were achieved by the sparrows introduced in the latter half of the nineteenth century in North and South America, South Africa, Australia and New Zealand. For example, the first successful introduction of House Sparrows in North America took place in New York in 1852; by the end of the century the species was present northwards to the limits of cultivation in Canada, and had penetrated the Mexican border to the south. Although some of this increase can be attributed to secondary releases, most of it must have occurred by natural post-breeding dispersal. The expansion continues, and House Sparrows have recently reached the north of Venezuela, having become established along the Caribbean coast from Maiquetía (Caracas Airport) in the east to the Paraguaná Peninsula in the west. They are now also approaching the south of the country from Colombia, having reached there from Chile, where they were introduced in 1904, and through Amazonia, in Brazil, where they have spread north from Rio de Janeiro, in which they were released in 1905.

The Eurasian Tree Sparrow has not been so dramatic a colonist as has its congener, but it has nonetheless expanded its range in the last 150 years over the archipelagos of South-east Asia and the islands of the Mediterranean. There is little doubt that some of this was a consequence of deliberate introduction, but equally much of it was a result of natural spread through post-breeding dispersal, and has included the phenomenon of individuals taking involuntary rides on ships. This has occurred also with the House Sparrow, and even to the extent, it is reported, of hitching lifts on inter-island aircraft in the Azores. A juvenile House Sparrow, which boarded PanAm Flight 811 from Los Angeles to Sydney on 4th July 1981 (Independence Day!), was not welcomed by the Australian Quarantine & Inspection Authorities in Sydney, who promptly dispatched it!

This spread by dispersal is by no means limited to the introduced species. The Southern Grey-headed Sparrow has spread over much of the former Cape Province, in South Africa, since about 1950, an expansion of range of 800 km in only 35–40 years. There is no indication that this was in any way deliberately assisted by man, although it may, of course, have been triggered by changes in land use.

Less is known about the movements made by members of the other genera of the family. Most of the bush-sparrows either perform limited migratory movements or are nomadic outside the breeding season. The Pale Rock-sparrow of the monotypic genus *Carpospiza*, on the other hand, is almost completely migratory, breeding in south-east Turkey, the Levant and south-west Asia and wintering mainly in the Arabian Peninsula and north-west Africa. In the winter months, the snowfinches remain at high altitudes close to the snow-line or move into high-lying settlements, whereas the ground-sparrows breeding at high altitudes are more nomadic, descending to lower elevations or withdrawing to the outskirts of settlements in the winter.

Relationship with Man

The true sparrows, those in the genus *Passer*, have a closer relationship with humans than any other genus of wild birds, and 17 species out of the 26 have been recorded nesting on man-made buildings and feeding around habitations. In contrast, the other genera in Passeridae are much less associated with man. The rock-

All passerid nestlings are fed an exclusively animal diet to begin with, though their parents may bring them an increasing amount of plant food towards the end of their time in the nest. In their first few days, ***Eurasian Tree Sparrow*** *nestlings are fed on aphids and other small insects and spiders. As they grow, the size of the prey increases to include caterpillars, grasshoppers (Orthoptera) and beetles (Coleoptera), particularly weevils (Curculionidae). While the chicks are small, the parents strip the prey of hard parts such as the legs and wing cases.*

[*Passer montanus montanus*, Berbegal, Huesca, Spain. Photo: Ricardo Vila]

sparrows and bush-sparrows tend to occupy rough uncultivated land or light woodland, where they make little contact with man; similarly, the snowfinches and ground-sparrows live at high altitudes, where man has had little impact on the environment, although some species do move close to settlements to feed on waste and on seeds and insects in the dung of domestic herbivores. Three of these have been recorded as nesting on houses, although this habit is much less frequent in occurrence than is the case with *Passer*.

The association of the true sparrows varies from one species to another. The House Sparrow, for example, lives almost exclusively in complete dependency with man, not only living in built-up areas, including the environment of farms, but also nesting in buildings and at times even moving into the buildings themselves, and in the eastern part of its range the Eurasian Tree Sparrow behaves like a complete "house sparrow". With the other species, such as the Spanish Sparrow, the Pegu Sparrow, the Cape Verde Sparrow and the African grey-headed sparrow superspecies (see Systematics), to name just a few, the association is a more casual one, only a proportion of the population occupying the built-up environment.

In the tropics, some widely distributed species can be found breeding somewhere in their ranges at almost any time of the year, according to the local rainy season. The ***Yellow-throated Bush-sparrow****, for example, breeds from August to November in northern South Africa, October to January in eastern South Africa, and January to February in Namibia.*

[*Gymnoris superciliaris flavigula*, Marondera, Zimbabwe. Photo: Peter J. Ginn]

Perhaps unsurprisingly, evidence of the close relationships with man of the House Sparrow and the Eurasian Tree Sparrow goes back a long way. House Sparrows are mentioned in the Old Testament of the Christian bible, first written down in ancient Hebrew 200–300 years after Christ, and the first mention of the Eurasian Tree Sparrow is in the *Kojiki*, the earliest written book in Japanese, which is dated to the year 712. It is not certain if the words used, *tsippor* in Hebrew and *suzume* in Japanese, refer specifically to the two sparrows in question or merely to generalized small, brown birds, but from the context in which they are used the latter seems the more likely. There is no such doubt, however, about the birds appearing in the painting "Sparrows in Rice Paddy" by the Chinese artist Han Ruazhuo, who was active in the period 1110–1125; they are Eurasian Tree Sparrows. The attitudes of humans towards sparrows range from one of hatred to one of affection and love, with several of the species regarded by farmers as pests in cereal fields, or valued as food, or as laboratory animals, or as pets, and some also as subjects of art and holding a place of affection in the hearts of many human city-dwellers.

The designation of the House Sparrow as a pest led to the formation in many parishes in England of what were termed "Sparrow Clubs", dedicated to the extermination of the birds; such clubs were in existence from the sixteenth to the nineteenth centuries, paying bounties for the destruction of eggs, nestlings and free-flying sparrows. In Germany, massive poisoning campaigns were carried out in the period immediately after the Second World War. More recently, similar campaigns to destroy roosts and breeding colonies have been launched against Spanish Sparrows in the Central Asian republics and against the Sudan Golden Sparrow for it depredations on crops of the small millet and sorghum (*Sorghum*) in central Africa. This is a particular problem with these two sparrow species, which can gather in immense concentrations and cause significant local damage, in some cases even total loss of the crop. Control measures have been taken, for instance the felling of the trees used for nesting as well as feeding the birds with poisoned grain in Kazakhstan and Kyrgyzstan, and setting fire to roosts in Sudan; the extent to which

Since the complete breeding cycle takes only four to six weeks, there is plenty of opportunity for several broods to be raised in areas where a relatively long spring is followed by a mild early summer. The male takes on most of the work of feeding the fledglings while the female incubates the second clutch. Although sometimes considered a hybrid between the House (Passer domesticus) *and Spanish Sparrows* (P. hispaniolensis), *the* ***Italian Sparrow*** *appears to have a shorter breeding season than either of these species. It rarely raises more than one or two broods, because of the short spring in Italy and the Mediterranean islands where it breeds. Like the Italian Sparrow, the Spanish Sparrow is adapted to breeding in areas with a Mediterranean-type climate, where a short, wet spring is followed by a long, hot, dry summer, in which vegetation dies back and insect numbers are reduced. Some populations of Spanish Sparrows, particularly of the eastern race* transcaspicus, *follow the spring, raising their first broods in the southernmost part of the range, and moving north in search of suitable conditions to raise a second and even a third brood. These successive breeding colonies are quickly assembled, with the nests packed tightly together, as in sedentary populations of this species. The same sites may be used in subsequent years, or not, if conditions are better elsewhere. This nomadic behaviour enables Spanish Sparrows to breed concurrently with sedentary populations of House Sparrow at times when food availability is at its peak and sufficient for both species.*

[*Passer italiae*, Peccioli, Tuscany, Italy. Photo: Daniele Occhiato]

these have been effective is not known. It is worth noting that studies of the Sudan Golden Sparrow in Niger in the 1980s revealed that this species did not damage rice fields, even at the end of the dry season, because the birds preferred to take seeds from the ground. Moreover, this sparrow consumes injurious insects and feeds its nestlings with locusts (Acrididae). It is considered, therefore, that, while this species may have a small adverse impact locally, it should not be regarded generally as a pest, and traditional bird-scaring methods should be sufficient to prevent flocks from causing serious damage to crops.

It is important to note that sparrows, when feeding their young, take considerable quantities of what are considered pest insects, so that it is difficult to strike an economic balance. The practice of giving bounties in England has long since been abandoned, and it can be concluded only that it was ineffective in controlling the number of birds. This is borne out by the results of an experiment undertaken on a large scale in China. In 1958, the country's then leader, Mao Tse-tung, designated the Eurasian Tree Sparrow an enemy on the grounds that, in China, these birds consumed sufficient rice annually to feed 60,000 people. In April of that year, a three-day campaign, involving three million citizens, was waged against the sparrows, destroying a significant proportion of the species' population. The expected gain in rice production, however, did not materialize, because of increased losses through insect attacks, and the idea was quickly forgotten. The Eurasian Tree Sparrows soon regained their original numbers and rice production recovered to its normal level. It was not, however, until 1999, when Mao was safely dead, that the species was afforded full protection in that country.

Sparrow pie was a common country dish in England up to the time of the First World War. Although sparrows have since disappeared from the menu in that country, they are now being offered as a delicacy in restaurants in the Latin countries, frozen birds being imported from China in large numbers, said to exceed six million per year, despite the protected status that they were given in 1999 after the Mao campaign debacle. The flesh and, most particularly, the brain of sparrows had a reputation for increasing sexual potency. This applied both to the Eurasian Tree Sparrow in China, where the species was known as the "hemp bird" for the inclusion of *Cannabis* seeds in its diet, and to the House Sparrow in Europe, no doubt for its reputation for lechery, which can be traced back as far as Aristotle, who lived in the period 384–322 BC.

It is significant how man's attitudes towards the House Sparrow have changed over the years. In 1559, the Lutheran pastor of Dresden, in Germany, was commended "for having put under ban the sparrows, on account of their extremely vexatious chatterings and unchastity during the sermon to the hindrance of God's word and Christian devotion". Four hundred and twenty years later, the Rector of a church in Lincolnshire, in England, was roundly condemned for having a sparrow in his church shot because it was interrupting a classical guitar concert. A mere twenty-six years after that, a television company in the Netherlands was fined for having a sparrow shot for interfering with an attempt to establish a world record in collapsing a row of more than four million dominoes.

Because it is perceived as a pest, has been unprotected in most countries, at least until very recently, and is easily taken from the nest and reared in captivity, the House Sparrow has been used extensively, particularly in the USA, as a laboratory animal. It has been the subject of physiological studies, including photostimulation experiments examining the effects of different cycles of light and dark on sexual development, metabolic requirements under controlled conditions, intelligence tests, and so on. In addition, many eggs, nestlings and free-flying individuals have been sacrificed for analysis for environmental contaminants such as heavy metals and polychlorinated biphenyls (PCBs), for the presence of pathological organisms and the effect of these on the development of the nestlings, and for the possibility that the birds may act as carriers of the latter, with the potential for transmission to man and his domestic animals.

The House Sparrow holds a strong place of affection in the hearts of many town-dwellers for bringing life to the urban environment and for its cheeky behaviour. This has been demonstrated by letters to the press and politicians, following the recent decline in the species' numbers, and in Britain, at least, these have resulted in questions in Parliament asking Her Majesty's Government what is being done about the situation. This is not merely

Possibly because of the limited availability of food at higher altitudes, the ***White-winged Snowfinch*** *has a longer fledging period than lowland members of the family. The fledglings are fed by both parents for around two weeks after leaving the nest. The young undergo a complete post-juvenile moult, beginning 1–3 months after fledging, at which point they become almost indistinguishable from the adults. Adults have a single annual post-breeding moult. Studies of House* (Passer domesticus) *and Eurasian Tree Sparrows* (P. montanus) *suggest annual productivity of 3–10 fledged young per pair per year. Adult life expectancy is less than two years, although ringed Eurasian Tree Sparrows have lived for four years, Spanish Sparrows* (P. hispaniolensis) *for eight, and House Sparrows 13 years in the wild.*

[*Montifringilla nivalis nivalis*, Dolomites, Italy. Photo: Menno Hornman]

*At the same time as extending its range in northern and southern Europe and South-east Asia, at least partly as a result of deliberate or accidental introductions, the **Eurasian Tree Sparrow** has undergone a massive decline in parts of its natural range in Britain and adjacent mainland Europe, and Japan. This is thought to be the result of the intensification of agriculture, with increased use of pesticides and herbicides, and the change from spring to autumn sowing of cereals, so that spilt grain and weed seeds are no longer available over the winter. Conservation measures such as provision of winter food and nestboxes appear to have stabilized the situation in Britain, and the species is beginning to show a modest recovery.*

[*Passer montanus*, Hanko, Finland. Photo: Dick Forsman]

a matter of sentiment, but also a reflection of the underlying worry that the House Sparrow is the modern equivalent of the miners' canary, giving us the message that what is happening to the urban environment today may affect humans tomorrow. One must not, however, overlook the fact that the sparrow has a bad reputation among gardeners because of its predilection for tearing flower petals, particularly those of yellow crocuses (*Crocus*), in the spring. This has been explained as being wanton destruction, but it is difficult to attribute wanton behaviour to animals other than man. It seems more likely that the sparrows are, in fact, eating the petals as fresh vegetable matter or obtaining some moisture from them; the behaviour is more common in dry springs, giving some support to the latter hypothesis. A possibly more significant concern is that sparrows, with their close association with human beings, could be potential transmitters of disease both to people and to their domestic animals. House Sparrows are hosts of the poultry red mite (*Dermanyssus gallinae*) and the chicken flea (*Ceratophyllus gallinae*), both of which are disease-vectors for domestic poultry. Further, these birds are carriers of the West Nile Virus, a flavivirus borne by mosquitoes (Culicidae) that causes encephalitis, and the Eurasian Tree Sparrow is a carrier of avian influenza, including the highly pathogenic H5N1 strain, which can be fatal to humans. While there is no evidence to show that sparrows have acted as vectors in the transmission of diseases to man and his stock, and the chance of contracting disease from them is probably very small, the potential risk cannot be completely discounted.

Abandoned sparrow chicks on the ground are a not unfamiliar sight in areas of human habitation, and many have been adopted as pets. Stories abound in the literature, going back to Roman times. The poet Catullus, whose life probably spanned the years 84–54 BC, wrote a dirge on the death of a pet sparrow, in this case no doubt an Italian Sparrow, belonging to his mistress, Lesbia. This was followed some fifteen centuries later by another mock heroic dirge by the English poet John Skelton, who lived in the second half of the fifteenth century and the early sixteenth century; his poem on the death of a pet sparrow belonging to a certain Jane Scrope is entitled *Lament for Phyllypp Sparrow*. Perhaps the most famous of these pets, however, is Clarence, the hero of *Sold for a Farthing*, a biographical story of a sparrow written by Clare Kipps; Clarence lived with his mistress for a remarkable twelve years. Many others tales must have gone unrecorded.

Finally, two species of sparrow have an important place in the world of art. The Eurasian Tree Sparrow has for centuries been an inspiration for Oriental painters, and many of their works are a source of delight for the way in which they have captured the essence of the bird in a few simple brush strokes. The famous sixteenth-century Japanese scroll "Kotohta, the Sparrow", which depicts the fable of how Kotohta was religiously awakened and became a Buddhist monk, is a delight not only for the Eurasian Tree Sparrows, but also for many other easily recognized species. Sparrows appear much less frequently in western art, one exception being the *Madonna del Passero*, "Our Lady of the Sparrow", painted by the Italian Baroque artist Guercino (1591–1666), the subject again being, as it happens, an Italian Sparrow. In contrast, sparrows feature much more frequently in European literature, dating back, as already mentioned, to the Roman poet Catullus and extending right up to the present day, with a recent poem by the former British Poet Laureate, Sir Andrew Motion, inspired by the decline in the population of House Sparrows.

Status and Conservation

No species in the family Passeridae is globally threatened, although there have been some recent major changes in the range and numbers of some species. These changes have involved mostly increases, both through deliberate introductions by man and as a result of alterations in the environment that have favoured those species closely associated with humans, particularly members of the genus *Passer*.

Introductions of animals in countries outside their natural range date back to the early history of man, but they received an enormous boost in the middle of the nineteenth century when immigrants from Europe began the process on a large scale, with the formation of "acclimatization societies" dedicated to this activity. Introductions were made for a number of reasons, including aesthetic ones, but also as a source of food and for the control

of insect pests. Perhaps the most successful introduction of all avian species has been that of the House Sparrow, in many cases because it was mistakenly thought to be predominantly an insectivore. This species, with its close association with man, quickly established itself, occupying a niche that had not been filled to anything like the same extent by any native species. As a result, the House Sparrow has become one of the most widespread, and possibly the most numerous, species of terrestrial bird. Another *Passer* that has been successfully introduced, although by no means to the same extent, is the Eurasian Tree Sparrow. The range expansion of these two species is still in progress today, not so much through continued introduction, but adventitiously by the birds hitch-hiking on board ships and even on aircraft (see Movements), and by natural spread. Involuntary hitch-hiking by House Sparrows is a well established phenomenon. The colonization of the Falkland Islands in 1919 was evidently the result of about twenty individuals of this species travelling aboard four whaling vessels sailing from Montevideo, in Uruguay, to Stanley, in the Falklands. An even more extraordinary trip was taken by a group of House Sparrows that boarded a ship at Bremerhaven, in north Germany, on 14th July 1950 and did not disembark until the ship reached Melbourne, in south-east Australia. In both of these cases, the birds must have been provided with food, but they were not deliberately taken on board.

A second major cause of range extension has been the alteration of the environment. These have involved primarily farming activities that have increased the food resources for these granivores, increasing urbanization, and deforestation that has expanded the habitat favoured by the true sparrows, with their close association with man. These changes have had such an impact that it is worth looking in detail at a few specific examples that illustrate the dynamism of the genus *Passer*.

The spread of the House Sparrow, one of the most sedentary of all wild birds (see Movements), in colonizing new territories at rates of 15–80 km per year has been quite remarkable. Some of this spread, as, for example, that in North America, has no doubt been assisted through translocations by humans, but, even allowing for this, it is still worthy of study as a significant phenomenon in its own right. A recent example is the colonization of Amazonia, in Brazil. The species was introduced in Rio de Janeiro, in south-east Brazil, in 1905. Farther north, it was first recorded in Brasília in 1959 and in Recife in 1963. How it reached these places is not known, but they acted as the two centres from which the species spread to occupy many of the inhabited parts of Amazonia, extending as far west as Manaus, where it was first noted in 1987. Of course, it is not easy, especially in places not commonly visited by interested ornithologists, to distinguish between first occurrences and first reports, but one can assume that the pattern of the spread must have been dependent on deforestation and a growing settled human population. Even more recently, French Guiana was colonized in 1994 and Venezuela in 1996, so the expansion of range is still very much continuing.

A similar recent expansion of the Eurasian Tree Sparrow into the archipelagos of South-east Asia occurred at approximately the same time. Again, the specific details are not known, but the colonization is similarly the result of deliberate introductions, assisted by inadvertent ship-borne immigrants and natural spread. The Eurasian Tree Sparrow has been spreading also in the west of its range, where it has recently colonized Sardinia. The first breeding record on this Mediterranean island was in 1898, the birds either having been deliberately introduced or having arrived as ship-borne immigrants from Naples, on the Italian mainland. Sixty years elapsed with little change and then, within the space of a few years, the sparrows began to spread into coastal towns around the island, displacing the Spanish Sparrow from the built-up environment.

With over 65% of the species in the genus *Passer* associated with man, a greater proportion than in any other passerine genus, it is perhaps not surprising that they have responded strongly to changes in the environment resulting from human activities. In addition to those mentioned above, four other species have shown increases in range and numbers as a result of such effects. The Pegu Sparrow has colonized the Malay Peninsula from Thailand in the last hundred years, massive deforestation having created continuous corridors along which the species has been able to spread. The Dead Sea Sparrow, of which Canon H. B. Tristram once wrote "this bird is the most limited in its range and the scarcity in numbers of individuals", has achieved a significant expansion in its distribution in Israel and Turkey since the 1950s and 1960s. In Israel, at least, this is

*The **Socotra Sparrow** is a restricted-range species, confined to the Socotra Endemic Bird Area. It readily associates with human settlements, and is abundant on the island of Socotra itself, with around 250,000 individuals. In contrast, the paler race* hemileucus, *endemic to the 130-km² island of 'Abd al Kuri, is uncommon, probably numbering only about 1000 birds. This is significant, as it has been found to be genetically divergent from the nominate race, possibly representing a separate species. The Socotra Sparrow is part of a complex of rufous sparrows, nowadays normally considered to constitute six species but sometimes still all treated as conspecific.*

[*Passer insularis insularis*, Socotra. Photo: Hanne & Jens Eriksen]

probably the result of the increase in irrigated land that led to increases along the Jordan River of grasses, particularly canary grasses (*Phalaris*), the seeds of which are the principal food of this sparrow, together with the creation of dead trees, which are its principal nesting site, in areas flooded for fish ponds. Likewise, the Spanish Sparrow has benefited from intensive irrigation and rice cultivation in the valleys of the River Guadiana, in Extremadura, in south-western Spain, and the River Tagus, in southern Portugal. A final major extension of range has been that of the Southern Grey-headed Sparrow into the former Cape Province of South Africa, starting in the 1950s. There is no obvious reason for this spread, but it seems most likely that it is associated with subtle changes in land use and possibly also increasing use of buildings for nesting, as the sparrow has moved into farmland from its original woodland habitat.

In contrast to the range extensions by members of the genus *Passer*, the other genera in this family, and particularly the high-altitude snowfinches and ground-sparrows, whose habitat has been little altered by humans, have shown negligible change in their distribution and numerical status. Nevertheless, the White-winged Snowfinch has benefited from food scraps provided by people during the winter months at ski resorts.

Two species that have suffered minor declines are the Desert Sparrow and the Common Rock-sparrow. The eastern subspecies of the former, *zarudnyi*, has become extinct at the western edge of the Dasht-e-Lut, in Iran, and is decreasing in Turkmenistan and Uzbekistan. The African population in the Sahara, on the other hand, seems to be stable, having recently been rediscovered in Sudan, whence it was originally described and where it was thought to have become extinct. This species is, however, an erratic breeder, populations sometimes disappearing from one area but appearing in another where the species has not previously been reported, making it difficult to determine its true status. The Common Rock-sparrow has lost ground in the north of its range, both in Germany, where it bred regularly up to the 1920s, and in France; a similar trend is apparent on Madeira. These declines are possibly associated with loss of habitat to agriculture. Other possible causes of the rock-sparrow's disappearance from parts of its European range have been suggested. These include, especially, climatic changes, but other contributory factors may have been the direct killing of the birds, for collecting purposes, the restoration of old buildings and the felling of diseased fruit trees.

In the latter part of the twentieth century, however, a major and unexpected change was recorded in the populations of the two most widespread members of the family. A massive decline in the numbers of both the House Sparrow and the Eurasian Tree Sparrow was recorded in the British Isles and the nearby part of mainland Europe from Germany to Belgium. Both of these species had been increasing in farmland since the end of the Second World War. For example, the Eurasian Tree Sparrow, which in Britain is largely restricted to farmland, increased six-fold between the mid-1950s and the mid-1960s. Then, starting in about 1980, the numbers of both species crashed, the Eurasian Tree Sparrow to approximately the same level as that in the 1950s, and the House Sparrow by about 60%. These changes were almost certainly brought about by an increase in cereal production through increased application of chemical fertilizers, followed by the intensification of agricultural practices: the change from spring sowing to autumn sowing of cereals, with the concomitant loss of spilt grain and weed seeds over the winter; increased use of herbicides and pesticides, with a consequent reduction in the invertebrate fauna; more effective harvesting; the disappearance of stack-yards and improved storage, reducing the grain available to the birds; and the change from haymaking to silage production, with the grass cut before it has time to set seed. This has resulted not only in a reduced availability of the seeds that are the main food of the adult sparrows, but also, because of a decreased variety of plants and increased pesticide use, in a reduction in the invertebrates that are essential for the rearing of the young. Over the same period, there was an increase in the population of House Sparrows in the built-up environment, the prime habitat for the species, through increasing urbanization. Then, in about 1990, and independently of the farmland population, a major decline set in, leading to the House Sparrow's virtual extinction in the centre of large conurbations, at any rate in Britain, and a patchy decline in different types of residential areas that still, towards the end of the first decade of the twenty-first century, shows little sign of coming to an stop. A number of factors are probably involved in the urban decline, the major one being a decrease in the availability of invertebrates as a consequence of increased cleanliness and a decrease in the amount of native green vegetation. Although initially the urban House Sparrow decline began in north-western Europe, the same now appears to be occurring in towns in eastern Europe, Israel, India and the USA; and with the Eurasian Tree Sparrow in Japan.

*Another restricted-range member of the rufous sparrow group, the **Cape Verde Sparrow**, or Iago Sparrow, is confined to the Cape Verde Islands, some 5000 km from any of its nearest relatives. While the full specific status of other rufous sparrows is still disputed, the Cape Verde Sparrow has significant morphological and behavioural differences, including distinct sexual dimorphism. It occurs in treeless habitats, and nests in holes in walls and lava cliffs, while other rufous sparrows nest in trees. It is common across most of its range, though sporadic on some smaller islands, and mysteriously absent from the relatively large island of Fogo.*

[*Passer iagoensis*,
Santo Antão,
Cape Verde Is.
Photo: Dick Forsman]

Following its discovery in 1844, the ***Sind Sparrow*** *was not reported for a further 34 years, probably because of confusion with the House Sparrow* (Passer domesticus). *Although it resembles this species quite closely, it is some 20 mm shorter than the sympatric House Sparrow race* indicus. *Although it is a restricted-range species, increased tree-planting along canals and roadsides in the Indus plains has created new habitat, which has enabled the Sind Sparrow to increase significantly in recent years.*

[*Passer pyrrhonotus*, Harayana, India. Photo: Amano Samarpan]

It has been suggested that House Sparrows become adapted to local climatic conditions, and that severe and abrupt departures from these, such as persistent sub-zero temperatures, can cause serious mortality among the population. This certainly seemed to be the case in north-east Spain, when the normally mild winter climate was upset by a very hard winter in 1984–1985, leading to significantly higher mortality.

Despite the fact that the House Sparrow has been placed on the UK Red List of threatened species, is categorized as "Near-threatened" in Germany, and has been given protected status in the Netherlands, this is still a very minor part of the species' population, which on a world scale is under no serious threat and is still extending its range in many parts. This is apparent in the following lines from the Australian John Manifold's poem *Outer Suburbs*:

"It seems that you can't have gracious living and
Goannas. Shiny villas multiply
On what were quite attractive bits of land
And we'll be getting sewerage by and by.

Down where Macpherson's smithy used to stand
They've built a supermarket on the sly.
'It's progress', says my neighbour: 'Things expand'
But living creatures are in short supply.

We haven't had goannas in the yard
For six or seven years. They were the first
To leave, and then the frillies. That was hard.

The only newcomers are oversexed
Damned greedy sparrows, breeding fit to burst.
They drove the wrens away. It's our turn next."

Afghanistan's only endemic bird species, the ***Afghan Ground-sparrow*** *is only known to breed at scattered localities in the mountains, although there is a non-breeding record from Turkmenistan. It occurs in the Band-e-Amir Important Bird Area, which has been declared Afghanistan's first national park, though it still lacks any real management and protection. A potential UNESCO World Heritage Site, Band-e-Amir could provide future revenues from tourism, which would help cement its conservation status, but would need to be strictly controlled if it is not to damage the fragile mountain habitat on which this and other species depend.*

[*Pyrgilauda theresae*, Hazarajat, Afghanistan. Photo: Raffael Ayé/Wildlife Conservation Society]

Conservation measures for the Eurasian Tree Sparrow, in particular the provision of winter food and the erection of nestboxes, appear to have stabilized the situation in Britain, and the species is beginning to show a modest recovery. Nevertheless, there are still many parts of its former range in Britain where it remains an extreme rarity.

PLATE 48

inches 3
cm 8

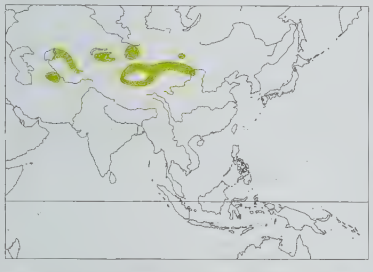
Genus *PASSER* Brisson, 1760

1. Saxaul Sparrow

Passer ammodendri

French: Moineau des saxaouls **German**: Saxaulsperling **Spanish**: Gorrión del Saxaul

Taxonomy. *Passer ammodendri* Gould, 1872, Turkestan = Djulek, above Kyzyl Orda, on the Syr Darya, Kazakhstan.



This species suggested as having evolved from an isolated population of sparrows in a steppe region in C Asia that remained unglaciated (25,000–15,000 years ago). Currently occurs in six allopatric populations, relationships among which, and the degree to which they are sufficiently distinctive to justify subspecific separation, are subject to debate. Additional proposed races are *korejewi* (described from E Transcaspia), included within nominate, and *timidus* (from Gobi Desert), subsumed into *stoliczkae*. Three subspecies currently recognized.

Subspecies and Distribution.

P. a. ammodendri Gould, 1872 – S Kazakhstan and N Uzbekistan (Kyzylkum Desert); Turkmenistan (Karakum Desert); possibly NE Iran.

P. a. nigricans Stepanyan, 1961 – SE Kazakhstan (Sary-Ishikotrau Desert), NW China (N Xinjiang) and extreme SW Mongolia.

P. a. stoliczkae Hume, 1874 – China from S Xinjiang (Kashgar and Taklimakan Desert) E to W Inner Mongolia and N Ningxia (Ordos Desert); SC Mongolia (Gobi Desert).

Descriptive notes. 14–16 cm; 25–32 g. Male nominate race has central forehead and crown to nape black, broad white supercilium from in front of eye, becoming tawny behind eye and fanning out on side of neck; lores black, narrow black line behind eye curving downwards around rear of pale grey ear-coverts, cheek paler grey to whitish; upperparts pale sandy grey, mantle with heavy black streaks, median and greater upperwing-coverts tipped white (broad wingbars); black bib from chin to uppermost breast, extending sideways on breast; underparts dirty white; iris dark; bill horn, becoming black in breeding season; legs pale brown or pinky brown. Female has basic pattern similar to that of male, but colours more muted and less contrasting, black areas greyer, tawny colour on head indistinct or absent; generally like a very pale female of *P. domesticus*. Juvenile resembles female, but crown less dark, chin and throat pale, lacking bib. Races differ mainly in plumage. *nigricans* male has blacker and more extensive streaking on mantle and upper back; *stoliczkae* is generally warmer brown above, most of supercilium and area behind ear-coverts gingery brown. Voice. Little reported. Call "cheerp cheerp", softer and more melodious than "chirrup" call of *P. domesticus*; "chip-ip-ip-ip-ip" as threat; alarm a nasal "quer quer", similar to that of *P. domesticus*; flight call "twerp". Song described as being pleasantly melodious, with varying intonation, but not loud.

Habitat. River valleys in sandy or stony desert and semi-desert, particularly associated with saxaul (*Haloxylon*), but found also in poplar (*Populus*) and tamarisk (*Tamarix*); extends into surrounding foothills and into cultivation and isolated habitations or small settlements without trees. Usually near water.

Food and Feeding. Seeds, particularly of saxaul, also insects. Nestlings fed with insects and insect larvae, particularly weevils (Curculionidae), ladybirds (Coccinellidae), grasshoppers (Orthoptera) and caterpillars of Lepidoptera. If water not available, will fly considerable distances several times a day to drink. Forages in mixed flocks with congeners outside breeding season.

Breeding. Season May–Jul; two broods. Nests as isolated pairs or in loose colonies, often mixed with *P. domesticus* and *P. montanus*. Both sexes take part in building nest, a loose construction of grass and rootlets, usually domed, with entrance on side or at top, lined with feathers, wool and fur, placed usually in hole or other hollow in tree, sometimes in nest of bird of prey, earth bank, wall or isolated building, these other sites probably now more frequently used owing to increasing removal of large trees by local inhabitants. Clutch 4–6 eggs; incubation by female, period 12–14 days; chicks fed by both parents, nestling period 13–15 days.

Movements. Mainly sedentary; flocks may make small local movements outside breeding season. Some populations possibly winter S of breeding range, but remain in desert regions.

Status and Conservation. Not globally threatened. Status poorly known; spends much time in foliage of bushes or trees, making it difficult to see. Some suggestion of range contraction, probably because of increased penetration by humans into semi-desert regions with irrigation. Claimed presence in non-breeding season in mountains of Iran–Afghanistan border requires corroboration; record from NE Iran in Apr 2004 suggests possible breeding. Owing to its sporadic distribution and desert habitat, this species presents little threat to agriculture.

Bibliography. Ayé (2008), Carruthers (1910a, 1949), Cheng Tsohsin (1987), Clement *et al.* (1993), Dementiev *et al.* (1954, 1970), Densley (1990b), Flint *et al.* (1984), Fu Tongsheng *et al.* (1998), Hartert (1904), Il'yashenko (1979), Ivanitskii (1997), Knystautas (1993), Piechocki & Bolod (1972), Schnitnikov (1949), Scott *et al.* (1975), Spangenberg (1959), Stahl (1995), Stepanyan (2003), Summers-Smith (1988), Vaurie (1964).

2. House Sparrow

Passer domesticus

French: Moineau domestique **German**: Haussperling **Spanish**: Gorrión Común
Other common names: Indian/Ceylon House Sparrow (*indicus*)

Taxonomy. *Fringilla domestica* Linnaeus, 1758, Sweden.

Presumed to have evolved from sparrow population that was trapped in Middle East during last Pleistocene glaciation (25,000–15,000 years ago). Forms a superspecies with *P. italiae* and *P. hispaniolensis*, and the three sometimes considered conspecific. Hybridizes with former in N Italy and with latter in SE Europe (Balkans), NW Africa, and Cape Verde Is (on São Vicente, where introduced), and evidently with *P. castanopterus* in Somalia; hybrids with *P. montanus* regularly reported, particularly where one of the two species rare and presumably has difficulty in finding a mate of its own species. Races form two groups, "nominate (or Palearctic) group" (also with *balearoibericus*, *tingitanus*, *niloticus*, *biblicus* and *persicus*) and "*indicus* (or Oriental) group" (also incorporating *rufidorsalis*, *hyrcanus*, *hufufae*, *bactrianus* and *parkini*), these groups intergrading where ranges meet. Migratory race *bactrianus* of the "*indicus*-group", and hence *indicus* itself, considered by some authorities worthy of full species rank, largely on grounds that it does not interbreed with resident nominate race (which has spread to C Asia in the last century) as well as differences in morphology and ecology; this, however, seems unsustainable as *indicus* intergrades with *persicus*, clearly a member of "nominate group"; lack of interbreeding seems more probably a temporal than a genetic effect. In North America, where introduced, birds from W USA described as race *plecticus*, supposedly paler than nominate, but differences apparently clinal; proposed race *maroccanus* (from Morocco) is synonymized with *tingitanus*. Nomenclature of introduced populations problematic, as many have differentiated sufficiently to be subspecifically separated from the parent stock; this certainly the case in North America, and also in S Africa (where some populations are derived from introduction of *indicus* from India that have interbred with smaller inoculum of nominate from Europe), and will obviously become an increasing problem as other introduced populations diverge. Twelve subspecies recognized.

Subspecies and Distribution.

P. d. domesticus (Linnaeus, 1758) – N & W Europe (S to Iberia and SC France) E in NC Asia (S to Ukraine, N Mongolia and NE China) to mouth of R Amur, locally also Sakhalin I and W & E Kamchatka.

P. d. balearoibericus Jordans, 1923 – Balearic Is, and S France E (excluding Italy and most Mediterranean islands) to WC Asia Minor.

P. d. tingitanus Loche, 1867 – NW Africa (Morocco E to NE Libya).

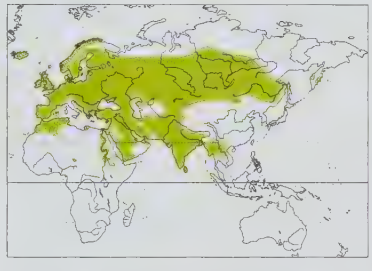
P. d. niloticus Nicoll & Bonhote, 1909 – Egypt (Nile Delta and Nile Valley).

P. d. biblicus E. J. O. Hartert, 1904 – SE Turkey, Cyprus and Levant E to NW Iran.

P. d. persicus Zarudny & Kudashev, 1916 – C Iran (S of Elburz Mts) E to W & S Afghanistan.

P. d. hyrcanus Zarudny & Kudashev, 1916 – SE Azerbaijan and N Iran (N of Elburz Mts).

P. d. indicus Jardine & Selby, 1831 – S Israel, S Palestine and much of Arabia E to SE Iran, peninsular India, Sri Lanka and C SE Asia (E to Laos).



P. d. rufidorsalis C. L. Brehm, 1855 – Sudan (Nile Valley S to 13° N) and E to Red Sea coast in Eritrea.

P. d. hufufae Ticehurst & Cheesman, 1924 – E Arabian Peninsula.

P. d. bactrianus Zarudny & Kudashev, 1916 – W Turkmenistan, NE Iran and S Kazakhstan E to Tien Shan, extreme NW China (NW Xinjiang) and NW Pakistan.

P. d. parkini Whistler, 1920 – from Kashmir E to Nepal.

Introduced (mainly nominate race and, in South Africa, *indicus*) in most other inhabited parts of the world, including the Americas and Australasia.

Descriptive notes. 16–18 cm, 20–39 g ("nominate group"); 14–16·5 cm, 21–33 g ("*indicus* group"). Very well-known species, those in urban environments tending to have dull, unkempt appearance, in contrast to those living in rural areas, which are quite striking and with more contrasts in plumage. Male nominate race breeding has characteristic head pattern, with grey crown, black line from bill back to eye, small white postocular spot (sometimes lacking), chestnut band behind eye and across nape and back of head, pale grey ear-coverts, and white or whitish cheek; upperparts brown, streaked black, lower back to uppertail-coverts brownish-grey; lesser and median upperwing-coverts chestnut, medians broadly tipped white, greater coverts dark brown to blackish-brown with broad chestnut edges and narrow buffish tips; flight-feathers blackish, secondaries and tertials edged pale brown, small pale patch at base of primaries; tail dark brown to blackish-brown, feathers with narrow buffish edges; chin and throat black, black extending variable distance onto breast and side and breast (black bib becomes more extensive in breeding plumage through abrasion of feather tips); otherwise pale grey below; iris dark brown; bill black; legs brown or dark brown. Non-breeding male differs from breeding in having chestnut colour of nape and most of black bib obscured by greyish feather tips, bill horn-coloured. Female is mainly dull brown, with lighter superciliary stripe, upperparts similar in pattern to male's but duller, lacking chestnut tones; chin and throat whitish (lacks dark bib), underparts paler; bill brownish, yellower base. Juvenile is like female, young male with hint of greyish bib. Races differ mainly in plumage tones, also in size, those in "*indicus* group" less robust and clearly smaller than those in "nominate group", as illustrated by e.g. mean wing length (male nominate 75·7 mm in England, 78·9 mm and 82·6 mm for two populations in N Germany): *balearoibericus* is generally paler than nominate, male cheek lighter grey, chestnut of nape and wing more cinnamon, grey of crown, lower back and rump paler (male wing c. 78 mm); *tingitanus* is similar to previous, but with black streaking on crown that becomes almost black with wear (male wing 78·8 mm); *biblicus* is paler than nominate (male wing 81 mm); *niloticus* is similar to last, but paler and smaller (male wing 75 mm); *persicus* also is similar, but paler (male wing 78·7 mm); *indicus* differs from nominate in strikingly white cheeks and very pale (almost white) underparts, chestnut of back paler, accentuating contrast of black streaks (male wing 74·4 mm); *rufidorsalis* has chestnut areas brighter and more extensive than last (male wing 72 mm); *hyrcanus* has chestnut areas darker, crown streaked (male wing 76·7 mm); *bactrianus* is paler than previous (male wing 76·1 mm); *parkini* has chestnut areas richer and darker than last (male wing 79·5 mm); *hufufae* is paler and greyer, chestnut pigments reduced (male wing c. 73·5 mm). Voice. Commonest vocalization a disyllabic "chirrup", used by male at nest-site to indicate ownership, and also by unmated male to attract a female, when a series of "chirrup" calls strung together to form rudimentary song (accompanied by wing-shivering). Threat indicated by "churr" followed by higher-pitched chatter or rattle; this gradually transformed to a more nasal "tew" as mood changes from threat to alarm. Soft "dee" used in solicitation between mates, and between adults and young. Individuals frequently gather in deep cover after feeding bout and join together in quiet, conversational chirping notes ("social song"); same heard at communal roost, this time less conversational-sounding and interspersed with threat and alarm calls as birds dispute favoured perch.

Habitat. Primarily associated with man, living around buildings from isolated farms to urban centres, showing preference for suburbs (where occurs at greater density and has greater breeding

On following pages: 3. Italian Sparrow (*Passer italiae*); 4. Spanish Sparrow (*Passer hispaniolensis*); 5. Sind Sparrow (*Passer pyrrhonotus*); 6. Somali Sparrow (*Passer castanopterus*); 7. Russet Sparrow (*Passer rutilans*); 8. Pegu Sparrow (*Passer flaveolus*); 9. Dead Sea Sparrow (*Passer moabiticus*).

success than in city centres and more rural areas). In S of range more frequently in open country, and has been recorded as breeding in small isolated colonies away from humans in Arabian Peninsula (also in Riverina District of New South Wales, in Australia, where introduced). In C Asian republics and Afghanistan, where mainly a summer visitor, confined to open country in area of overlap with resident *P. montanus* (latter having already occupied built-up habitat before arrival of present species); farther N, in Siberia, the two species live side by side in built-up areas. Lowlands to mountains; to 2300 m in Europe and to 4600 m in Himalayas; one record at 4900 m, in Peru, where introduced.

Food and Feeding. Mainly vegetable matter, especially seeds of grasses, cultivated cereals and low herbs, but also buds, berries and wide range of household scraps. Some animal matter taken, making up to 10% of diet in summer months. Is, however, a complete opportunist and takes very wide range of food items, including small frogs, small molluscs and crustaceans on shoreline. Nestlings fed for first three days with animal food, mainly aphids (Aphidoidea), weevils (Curculionidae), grasshoppers (Orthoptera) and caterpillars, later gradually changing to vegetable diet. Seeds collected from growing plants and from the ground. Catches arthropods by searching for them, although occasionally takes larger insects, such as butterflies (Lepidoptera), in flight, and dragonflies (Odonata) seized at rest when in semi-torpid state in cool early morning. Generally in flocks, often large ones outside breeding season.

Breeding. Feb–Sept, varying with latitude, but can be interrupted by high temperature and monsoon rains; up to three broods, and occasionally four. Field observations suggest strict monogamy, but DNA studies have shown that 10–20% of nestlings were not fathered by male of the pair feeding the young. Breeds mainly in loose colonies of 10–20 pairs, sometimes more; occasionally solitary. Nest-building started by unmated male, but once pair formed the female takes part, particularly in adding lining; nest consists mainly of plant stems, lined with feathers or other soft material, preferred site a hole in building, cliff or tree (material then filling cavity), but sometimes, particularly in S of range, in branches of tree (nest then about size of a football, domed, with entrance on side), and migratory populations in Asia breed away from man in hole in cliff or earth bank; is, however, extremely catholic in choice of site, and has been recorded as nesting on moving structures, such as nodding donkey in oil field, and even on moving vehicles e.g. car and small ship (the pair following these on their daily journeys and continuing to feed nestlings), and even lived and nested 640 m below ground in coal mine in England. Clutch 2–5 eggs, occasionally up to 8; incubation by both sexes, period 11–14 days; chicks fed by both sexes, nestling period 14–16 days; fledglings fed by both parents for up to c. 2 weeks. Overall breeding success from 33 studies was 48·5% (range 25–85%); most pairs raise about five young per year. One ringed individual lived for at least 13 years in the wild; mean annual survival rate in Europe 54%.

Movements. Mostly resident; some limited withdrawal of populations breeding at high latitudes and altitudes to less cold areas in winter. Small amount of juvenile dispersal in autumn; once individuals have settled in breeding area, they stay mainly within small range of 1–2 km in radius. Races *bactrianus* and *parkini* migratory, former spending non-breeding season in N parts of Indian peninsula, latter moving S to lower altitudes.

Status and Conservation. Not globally threatened. Generally common to abundant; one of the commonest passerines, natural range having been increased by introductions in most inhabited parts of the world. Breeding densities range from 2–5 pairs/ha at town edges to as high as 25 pairs/ha in farms with livestock, although marked decline in recent years in some areas. Rough estimates in 1980s–1990s gave following figures for breeding pairs: Russia 30,000,000, Spain 9,500,000, Germany 6,500,000 (5,600,000–11,000,000 in 2006), Belarus 5,500,000, Czech Republic 4,000,000, Ukraine 3,500,000, Bulgaria, Romania, Croatia and Turkey each 3,000,000, Slovakia 1,500,000, with European total of over 50,000,000 breeding pairs and perhaps a world population of c. 500,000,000 pairs. Since c. 1980, numbers have declined significantly in the highly developed parts of W Europe and North America (introduced), particularly in large urban centres (decreases of up to 95%) and farmland (decrease of c. 70%); for example, estimated breeding population in Britain in 2000 between 2,000,000 and 5,400,000 pairs, a reduction of 60–65% from the peak in c. 1980. As a result of decline, this species was red-listed in UK in 2002 and listed as "Near-threatened" in Germany, though still common despite this decline. Recent studies in Britain suggest that major reason for decline is decreasing availability of suitable vertebrate food necessary for rearing young, and possibly reduced fitness of those young that fledge successfully; has been proposed also that the conservation and habitat enhancement of even the smallest parks and gardens are likely key factors in addressing the decline of this species in many cities. More recently, evidence of decline in urban populations noted also farther E in range, in Ukraine and India. On the other hand, is still expanding its range in some areas, with spread S in Kazakhstan and Siberia, increasing reports from Thailand, and recent records from Japan (1990), Hong Kong (1994) and Seychelles (2004); further, has extended range S along R Nile in Sudan and spread E through Eritrea to Red Sea coast (at Massawa), and has established breeding populations in W Africa, where introduced, originating in Senegal (1970s) and now thinly distributed, mainly in coastal towns, from Mauritania S to Ivory Coast, also inland at L Chad; also in French Guiana (1994), Venezuela (1996), where at present restricted to coastal strip N of N Cordilleras, and Singapore (1997); in Canary Is, on Gran Canaria (1998), but these birds have now disappeared, presumably having been absorbed into local population of *P. hispaniolensis* through hybridization.

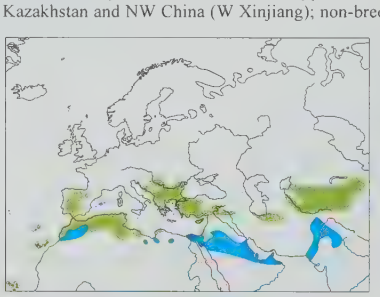
3. Italian Sparrow

Passer italiae

French: Moineau cisalpin **German**: Italiensperling **Spanish**: Gorrión Italiano
Other common names: Cisalpine Sparrow

Taxonomy. *Fringilla Italiae* Vieillot, 1817, Italy.
Forms a superspecies with *P. domesticus* and *P. hispaniolensis*, and the three sometimes considered conspecific. Hybridizes with former in N of range (along the line of the Alps) and with latter in S (rather broader zone S of Naples, possibly extending as far S as Malta and even Pantelleria). Has been treated variously as a race of one or other of those, as a stabilized hybrid between them, and as an independent species of N African origin that subsequently spread to Italy and became extinct in N African area of its origin. Appears distinctive in plumage, and treatment as distinct species based on argument that speciation of animals can occur only through geographical isolation, and not by hybridization. Although hybridization hypothesis plausible, and while origin remains uncertain, this taxon is most conveniently treated, as is currently common practice, as a separate species on grounds that population is stable and has resulted from events long past. Populations in Corsica, Sicily and Crete phenotypically similar to present species and included within it. Monotypic.
Distribution. Italy, Corsica, Sicily and Crete.



Descriptive notes. c. 16 cm; 23–30 g. Male is intermediate in plumage between *P. domesticus* and *P. hispaniolensis*: has chestnut crown, nape and hindneck, black lores, white cheek and ear-coverts; warm brown upperparts streaked black, lower back to uppertail-coverts grey; upperwing-coverts dark brown with broad chestnut edges, medians broadly tipped white, greaters with narrow buffish tips, flight-feathers blackish with broad buff edges; rectrices grey-brown with buffish edges; chin and throat to upper breast black (bib limited in extent, slightly larger than that of *P. domesticus*), rest of underparts pale whitish-grey; iris dark brown; bill black; legs flesh-pink to horn-brown. Female is mainly dull brown, with indistinct paler supercilium, upperparts as on male but duller, lacking chestnut, underside whitish to buffy white (lacks dark bib), bill browner; indistinguishable from female *P. domesticus*. Juvenile is like female. Voice. Disyllabic "chirreep" call used by male to proclaim nest-site ownership and in speeded-up version to attract a mate, more melodic than similar call of *P. domesticus* and more akin to that of *P. hispaniolensis*; suggested as better adapted to "natural" environments than to noisy "urban" ones. Other calls very similar to those of *P. domesticus* and *P. hispaniolensis*.
Habitat. Urban areas, farms and villages, including surrounding land, with preference for rocky habitats. Similar to that of *P. domesticus*, although probably less at home in urban areas, particularly well-vegetated ones (where it co-exists with and appears to be subdominant to *P. montanus*), and more in agricultural areas with extensive cereal cultivation. Unlike *P. domesticus*, occurs also in light woodland. Lowlands to 2200 m.
Food and Feeding. Principally seeds in agricultural areas, and domestic scraps near habitations; also some animal food, mainly insects, and small lizards regularly noted as being taken. Young fed with insects, mainly beetles (Coleoptera) and larvae of Lepidoptera, and seeds. Forages in small flocks.
Breeding. Not well recorded. Mar–Aug, mainly May–Jun; one or two broods, rarely up to four; appears to have shorter breeding season than *P. domesticus* and *P. hispaniolensis*. Breeds usually in loose colonies. Nest an untidy mass of dry grass, more compact than that of *P. domesticus*, domed, with entrance at side, lined with feathers; placed usually in hole in tree, building or rocky coastal cliff, or in base of nest of bird of prey, sometimes more openly in tree, e.g. at base of leaves of palm, or free-standing in branches of tree or on telegraph pole. Clutch 2–8 eggs, mostly 4–6; incubation by both sexes, period 11–15 days; chicks fed by both parents, nestling period 11–17 days; fledglings fed by both parents.
Movements. Largely sedentary; recovery in Italy of individuals ringed in S France (Camargue) and recovery on Corsica of one ringed on Italian mainland suggest that there can be significant dispersal.
Status and Conservation. Not globally threatened. Abundant; the most numerous bird species in Italy. Breeding densities 2–40 birds/10 ha; estimated population of 5,000,000–10,000,000 breeding pairs. Apparent decline noted recently, especially in urban areas.
Bibliography. Baumgart (2003), Brichetti (2008), Brichetti *et al.* (1993), Cramp & Perrins (1994), Dinetti (2006, 2007, 2008), Fulgione & Milone (1998), Fulgione, Aprea *et al.* (2000), Fulgione, Esposito *et al.* (2000), Fulgione, Procaccini & Milone (2000), Fulgione, Rippa *et al.* (2005), Fulgione, Ruschi *et al.* (1998), Hagemeijer & Blair (1997), Hartert (1904), Hudde (1997b), Johnston (1969), Lo Valvo & Lo Verde (1987), Lockley (1996), Massa (1989), McCarthy (2006), Meschini & Frugis (1993), Milone *et al.* (2002), Sorace (1993), Summers-Smith (1988), Thibault & Bonacorssi (1999), Töpfer (2006).

4. Spanish Sparrow

Passer hispaniolensis

French: Moineau espagnol **German**: Weidensperling **Spanish**: Gorrión Moruno
Other common names: Willow Sparrow

Taxonomy. *Fringilla hispaniolensis* Temminck, 1820, Algeciras, southern Spain.
Forms a superspecies with *P. domesticus* and *P. italiae*, and the three sometimes considered conspecific. Hybridizes extensively with former, and in S Italy with latter; hybrids with *P. montanus* also reported. Two subspecies recognized.
Subspecies and Distribution.
P. h. hispaniolensis (Temminck, 1820) – Iberian Peninsula, Sardinia, Greece and Balkans, W Asia Minor, E Atlantic islands (Madeira, Canary Is and Cape Verde Is) and NW Africa (Morocco E to NE Libya).
P. h. transcaspicus Tschusi, 1902 – Cyprus, E Turkey and Levant E to Iran, Afghanistan, S Kazakhstan and NW China (W Xinjiang); non-breeding also NW Indian Subcontinent.

Descriptive notes. 15–16 cm; 22–38 g. Male nominate race breeding has forehead to nape and hindneck deep chestnut, lores black (usually with short white supraloral line), white postocular spot, cheek and ear-coverts; upperparts streaked black and buffish-brown, paler line down each side of mantle and back, lower back to uppertail-coverts greyish-brown; upperwing-coverts chestnut, medians broadly tipped white, greaters with black centres and narrow whitish tips, flight-feathers black, edged sandy, pale patch at base of primaries; tail dark brown, bases of rectrices edged paler; chin to breast black, black continuing as heavy bold streaks down side to lower flanks (extent of streaking variable), rest of

underparts white; iris dark brown; bill black; legs pale pale pinkish or fleshy-brown. Differs from similar *P. domesticus* in having top of head chestnut (not grey), white postocular spot always present (not sometimes lacking), upperparts more boldly marked, and bib more extensive and continued on flanks as black streaks. Non-breeding male differs from breeding in having chestnut and black areas of head and much of black bib obscured by greyish feather tips, black areas on upperparts likewise, bill horn-coloured. Female is mainly dull brown to grey-brown, with lighter superciliary stripe (mainly behind eye), upperparts similar in pattern to male's but duller and browner, with less black and lacking chestnut tones (but normally rather more boldly marked than *P. domesticus*, although often inseparable in field); chin and throat whitish (lacks dark bib), underparts paler, with necklace of dark streaks that are continued down flanks; bill brownish, yellower base. Juvenile is similar to female, but markings somewhat less bold, and lacks necklace and streaks below; often inseparable in field from juvenile of *P. domesticus*. Race *transcaspicus* is very like nominate, and male almost identical, but freshly moulted individuals (particularly females) paler. VOICE. Call an almost disyllabic "tchweep", used by male to proclaim nest ownership, speeded up into continuous flow of rapidly repeated "cheeli-cheeli-cheeli" calls to attract a mate, louder and higher-pitched than similar calls of *P. domesticus*; can be heard at distance of up to several hundred metres. A similar, but softer call given at roost, when large numbers that collect together can produce quite a din. All other calls similar to those of *P. domesticus*, include conversational jumble of soft chirps in "social singing", nasal "chur-it-it-it" as threat, nasal "quer" or "quer-it-it" as alarm, "que que que" for contact.

Habitat. Predominantly moist, humid areas near water with trees and shrubs; normally associated with cultivation, extending in places into more arid steppe and semi-desert and penetrating urban areas where *P. domesticus* is lacking, e.g. Malta, Sardinia, Madeira, Canary Is. Outside breeding season frequently associates with *P. domesticus* in open areas, but is more nomadic than its congener. Normally in lowlands, but to 2750 m in Afghanistan.

Food and Feeding. Principally vegetable matter, mainly seeds of grasses, cultivated crops and low herbs, but invertebrates taken throughout year. Insects eaten are mainly caterpillars (of Lepidoptera), grasshoppers (Orthoptera) and flying ants (Formicidae); beetles (Coleoptera) apparently less important than for *P. domesticus*. Chicks fed almost exclusively with insects for first half of nestling period, followed by increasing proportion of plant material. May capture insects by searching on ground or among leaves of bushes and trees. Generally in small to large flocks.

Breeding. Season mainly Apr–Aug in W of range, from Mar in N Africa, and Aug–Oct and Feb–Mar in Cape Verde Is; in E of range moves N (following 25°C Jul isotherm) for successive broods, breeding from end May/early Jun in NE of range; 2–4 broods. Colonial, in W of range colonies of tens to several thousands, with up to c. 125,000 nests in one colony distributed over 60 ha in Morocco, generally even larger in E, with colonies of up to several hundred thousand pairs; nests packed closely together, sometimes over 100 in one tree. Nest built by both sexes, a loosely woven, roughly spherical structure 15–30 cm in diameter, of grass and other plant stems, lined with finer grasses and feathers, firmly attached to branches of tree, in lower part of large nest of bird of prey, crow (Corvidae) or heron (Ardeidae), or on pylon; much less commonly in hole in wall or building, such sites used particularly where *P. domesticus* absent. Clutch 2–6 eggs, occasionally up to 8; incubation by both sexes, period 11–14 days; chicks fed by both parents, nestling period 11–15 days; fledglings tended by both parents. Breeding success for individual nests estimated at 53–62%, but because of breeding strategy no data on annual productivity. Ringed individual survived for at least 9 years in the wild.

Movements. Variously resident, nomadic and migratory. Those on E Atlantic islands and some populations in S of range resident; partial shift S, e.g. in Ibera and NW Africa. In E, race *transcaspicus* mostly migratory, after breeding moving to S Afghanistan, Pakistan and NW India, some to Arabian Peninsula; arrives in Kazakhstan from mid-Apr to early Jun, leaving from late Sept to early Nov; vast numbers on passage through passes of W Tien Shan. In addition, dispersal by post-breeding flocks in search of food can involve distances of several hundred kilometres. Vagrants recorded in British Is and N Europe and, in S, accidental in winter S to 19° N in Morocco, S Saharan oases and N Sudan.

Status and Conservation. Not globally threatened. Common to locally abundant. Rough estimates in 1980s–1990s gave following figures for breeding pairs: Romania 500,000, Greece 400,000, Bulgaria 300,000, Malta 40,000, Spain and Portugal 30,000 each, with total for Europe of 1,500,000–2,500,000 pairs; several tens of thousands of pairs in Israel. Few population figures for E part of range, but extremely numerous in some areas; numbers migrating through Chokpak Pass, Kazakhstan, declined from average 35,200,000 in 1965–1981 to 11,400,000 in 2003–2005. Colonized Madeira, Canary Is and Cape Verde Is in 19th and 20th centuries; in SE Kazakhstan and NW China (Xinjiang), has extended range since 1940 as a result of increase in cereal cultivation. Increase in numbers and distribution noted since 1980 in Iberian Peninsula (Extremadura, in Spain; Alentejo, in Portugal), in Balkans, and in Middle East (where it has extended S to Saudi Arabia), and further increase also in extreme NE of range in Xinjiang, despite extensive attempts at control by local farmers; this increase and expansion largely the result of intensification of irrigated cultivation. In contrast, has declined almost to extinction on Madeira as a consequence of indiscriminate use of insecticides. Where its numbers are large, this species can become a serious pest of agriculture.

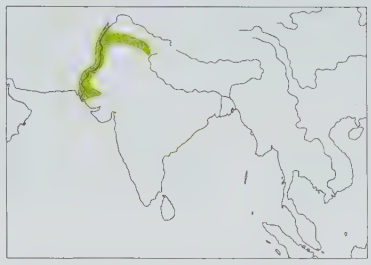
5. Sind Sparrow



Passer pyrrhonotus

French: Moineau du Sind **German**: Dschungelsperling **Spanish**: Gorrión del Sind
Other common names: (Sind) Jungle/Rufous-backed Sparrow

Taxonomy. *Passer pyrrhonotus* Blyth, 1845, Bahawalpur, Sind, Pakistan.
Thought probably to have evolved from a population of sparrows trapped in Indus Valley, which remained ice-free during last Pleistocene glaciation (25,000–15,000 years ago). Was in the past believed to be possibly a small race of *P. domesticus*. Monotypic.

Distribution. Indus Valley (and lower reaches of its main tributaries), in Pakistan, E in Punjab to Delhi area, in N India.

Descriptive notes. 12·5–13 cm. Male breeding has grey crown to hindneck, dirty grey ear-coverts and cheek, black lores, broad chestnut band behind eye curving around rear of ear-coverts and broadening on lower neck side; mantle and back upperparts rich brown, streaked black, scapulars chestnut with black centres, rump plain reddish-brown, uppertail-coverts grey; lesser upperwing-coverts chestnut, medians black with broad white tips, greater coverts blackish with broad brown-

ish edges and narrow buff tips; flight-feathers black, edged buffish to sandy, small buff area at base of primaries; tail greyish-brown, feathers finely edged buffish; chin and centre of throat to uppermost breast black, side of throat white, underparts pale grey, flanks washed light brownish, undertail-coverts whiter; iris dark brown; bill black; legs yellowish-brown. Differs from similar *P. domesticus* in smaller size, greyer ear-coverts, more distinct black streaking on back, reddish-brown rump, more restricted bib. Non-breeding male differs from breeding in having pattern somewhat obscured by greyish feather tips, bill base paler, horn-coloured. Female is mainly dull brownish, with lighter superciliary stripe, upperparts similar in pattern to male's but duller, chin and throat plain light greyish (lacks dark bib), underparts paler; bill brownish, yellower base; very like a small sleek female *P. domesticus*. Juvenile resembles female. VOICE. Poorly known. Male call a soft "chup". Song described as mix of whistles, chirrups, twitters and grating notes, more complex than that of *P. domesticus*; old report that song consists of the usual sparrow chirrups, but with a sharper note, often repeated, which resembles call of White Wagtail (*Motacilla alba*).

Habitat. Predominantly in riverine or swampy areas, occurring in wet tall grass, tamarisk (*Tamarix*) and acacia (*Acacia*) jungle; unlike majority of sparrows, is not particularly associated with humans.

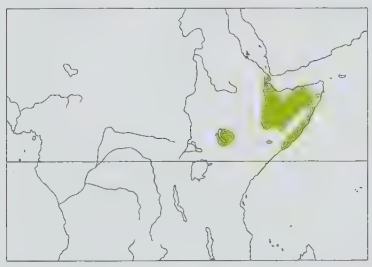
Food and Feeding. Mainly seeds, mostly of grasses and small herbs; also some invertebrate food, e.g. caterpillars of Lepidoptera. Forages in small flocks, of up to c. 20 individuals outside breeding season.

Breeding. Season Apr–Sept; two broods. Breeds in loose colonies. Nest a large, untidy globular construction of grass, reeds and coarse twigs, entrance on side or at top, placed in branches of low tree, particularly one standing in or overhanging water. Clutch 3–5 eggs. No other information available.

Movements. Resident. Report of "small *P. domesticus* with a characteristic high-pitched call" in E United Arab Emirates (Al Fujayrah) in Nov 2000 suggests possible S movement outside breeding season, but confirmation required.

Status and Conservation. Not globally threatened. Restricted-range species: present in Indus Plains Secondary Area. Locally common. Expansion E in N India relatively recent. Old reports from SE Iran (Sistan) require corroboration. Following initial discovery of the species, and despite considerable searching, 34 years elapsed before it was found again; this probably due to fact that its similarity to *P. domesticus* suggested that it was merely a small race of latter.

Bibliography. Ali & Ripley (1974), Bapat (1992), Clement *et al.* (1993), Currie (1909), Doig (1880), Harvey & Sharma (2002), Holmes & Wright (1969), Hume (1873, 1880), Rasmussen & Anderton (2005b), Roberts (1992), Scott *et al.* (1975), Summers-Smith (1988), Ticehurst (1922), Whistler (1911), Whistler & Kinnear (1949).



6. Somali Sparrow

Passer castanopterus

French: Moineau de Somalie **German**: Somalisperling **Spanish**: Gorrión Somalí

Taxonomy. *Passer castanopterus* Blyth, 1855, Somalia.
Has been considered to form a superspecies with *P. rutilans*, and sometimes treated as conspecific; similarities in plumage and morphology between the two likely a matter of convergence, rather than close relationship. Two subspecies recognized.

Subspecies and Distribution.
P. c. castanopterus Blyth, 1855 – Djibouti, Somalia and E Ethiopia (E from c. 41° E).
P. c. fulgens Friedmann, 1931 – extreme S Ethiopia and N Kenya (S to Kapedo and Marsabit).

Descriptive notes. 13–14 cm; c. 18 g. Male nominate race breeding has forehead to hindneck bright chestnut, lores and small area behind eye black, ear-coverts and cheek pale creamy grey; upperparts grey, mantle and back heavily streaked black; upperwing-coverts and most of scapulars bright chestnut, flight-feathers blackish, secondaries and tertials edged buffish, small creamy patch at base of primaries; tail dark grey, feathers edged brownish; chin and throat to uppermost breast black; underparts off-white to pale buffy grey; iris dark brown; bill black; legs pale brown to pinkish-brown. Non-breeding male differs from breeding in having plumage slightly obscured by whitish feather tips, bill horn-coloured. Female is mostly dull brown, lacking chestnut, with broad pale creamy supercilium, sandy-brown upperparts with some black streaking, wing much as for male, chin and throat white, underparts light buffish, bill yellowish with brown tip. Juvenile is like female, but paler. Race *fulgens* has chestnut of head brighter, strong yellow wash on cheeks and underparts. VOICE. Poorly known. Call a soft "chirrup", almost identical with that of *P. domesticus*.

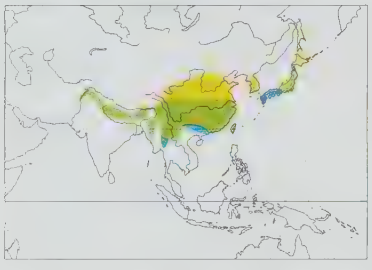
Habitat. Semi-arid to arid country with acacias (*Acacia*), and frequently in towns and villages, where it takes over role of *P. domesticus*; also rocky areas, including coastal cliffs.

Food and Feeding. Mainly granivorous, food including seeds of cultivated cereals, and has been recorded as feeding on spilt grain and on undigested grain in droppings from horses; also household scraps; also insects, e.g. termites (Isoptera) and caterpillars of Lepidoptera. Gregarious; outside breeding season forages in large flocks.

Breeding. Season Feb–Jul. Solitary or in loose colonies; sometimes in colonies of *P. euchlorus*. Open nest flask-shaped, loosely constructed from grass, lined with feathers, placed in hole in building or in branches of thorny tree or shrub. Clutch 4–7 eggs; young fed by both sexes. No other information.

Movements. Nomadic in large roaming flocks outside breeding season.

Status and Conservation. Not globally threatened. Uncommon to rare in Djibouti; locally common elsewhere in range. Very common, at least formerly, in Somalia; present status there not known, but possibly increasing. Rare in parts of Kenyan range. Opportunistic; spread inland in Somalia in early 1900s following the supply convoys of British army, feeding on scraps and grain spilt by the baggage animals, and more recently has exploited famine-relief centres. Nomadic post-breeding flocks can become sufficiently large to be a pest in cereal cultivation.



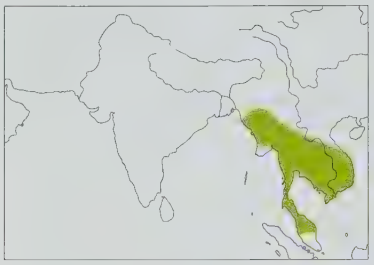
Bibliography. Archer & Godman (1961), Ash & Atkins (2009), Ash & Colston (1981), Ash & Miskell (1998), Britton (1980), Clement *et al.* (1993), Friedmann (1931, 1937), Fry & Keith (2004), Lewis (1981b), Mackworth-Praed & Grant (1960), McCarthy (2006), Redman *et al.* (2009), Ruelle (1992a), Summers-Smith (1988), Witherby (1905).

7. Russet Sparrow

Passer rutilans

French: Moineau rutilant **German**: Rötelsperling **Spanish**: Gorrión Rutilante
Other common names: Cinnamon (Tree) Sparrow, Ruddy Sparrow

Taxonomy. *Fringilla rutilans* Temminck, 1836, Japan.
This species probably evolved from an isolated sparrow population that was trapped in an ice-free refugium in Yangtze Valley during the last Pleistocene glaciation (25,000–15,000 years ago). Has been considered to form a superspecies with *P. castanopterus*, and sometimes treated as conspecific; similarities in plumage and morphology between the two likely a matter of convergence, rather than close relationship. Proposed race *batangensis* (described from W Batang area of Sichuan, in China) considered synonymous with *intensior*. Three subspecies recognized.
Subspecies and Distribution.
P. r. cinnamomeus (Gould, 1836) – NE Afghanistan E in Himalayas (mostly above 1800 m) to S China (S & SE Xizang and S Qinghai) and NE India (Arunchal Pradesh).
P. r. intensior Rothschild, 1922 – NE India (Assam), SC & S China, and N Myanmar E to N Laos and NW Vietnam.
P. r. rutilans (Temminck, 1836) – NC & E China, Korea, Taiwan, S Sakhalin I, S Kuril Is and Japan.



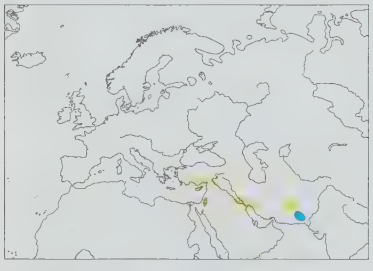
Descriptive notes. 14–15 cm; 13–23 g. Male nominate race breeding has top of head to hindneck and upperparts bright cinnamon-brown or russet, heavily streaked black on mantle; lores black, ear-coverts and cheek off-white; lesser upperwing-coverts as back, median coverts black with broad white tips, greaters blackish with broad buffish edges and narrow pale buff tips; flight-feathers blackish, secondaries and tertials edged buffish, small pale patch at base of primaries; tail dull brownish or grey-brown, feathers with narrow pale edges and tips; chin and throat black, underparts off-white; iris dark brown; bill black; legs pale brown to pinkish-brown. Non-breeding male is like breeding male, but plumage pattern partially obscured by pale feather tips, bill horn-coloured. Female is sandy brown to dull cinnamon above, with very conspicuous long, bright creamy supercilium, broad pale and dark stripes on mantle, white chin and throat, yellowish bill with dark tip; similar to female of *P. domesticus*, but more brightly marked, with far more striking supercilium. Juvenile is similar to female, but duller. Race *cinnamomeus* male has strong yellow tinge on cheeks and underparts; *intensior* is like last, but deeper russet tone above, yellow on face and underparts much paler. Voice. Main call a monosyllabic "cheep" or "chilp", used by male for proclaiming nest-site ownership; several notes may be strung together to form short musical song, "cheep chirrup cheeweep"; these among the most musical calls of any of the sparrows. Threat call "chit-it-it".
Habitat. In W of range occupies light woodland, terrace cultivation around edges of villages, and more open parts of built-up areas; montane, from c. 1000 m to 4300 m, breeding mostly to 2300 m, down to edge of plains, to c. 500 m, in non-breeding season. In E occurs in open woodland, forest edges and cultivation, descending to sea-level. Often in cultivated fields in winter months.
Food and Feeding. Principally seeds, including those of cultivated cereals, also small berries. Nestlings fed almost exclusively with animal food, mainly caterpillars and grubs. Obtains insect items by searching leaves and, to lesser extent, by seizing them in flight. Collects in large flocks in winter to feed on spilt grain and weed seeds in stubbles of cultivated fields.
Breeding. Season Apr–Jul; two broods. Solitary; not particularly colonial. Nest built by both sexes, an untidy collection of grass, lined with hair and feathers, placed in hole, mainly in tree, but also in house eaves or other cavity in building, in embankment or in stone wall, or in old nest of hirundine; in E of range also builds free-standing nest in branches of shrub. Clutch 4–6 eggs; incubation of eggs and tending of young by both parents; no further information.
Movements. Those breeding at high altitudes in Himalayas descend to 500–1000 m in winter. Farther E, migratory, with a general withdrawal from higher latitudes to areas S of breeding range, including N Thailand.
Status and Conservation. Not globally threatened. Common in W of range. Possibly decreasing in E parts of range, where formerly abundant as a passage migrant in flatlands of N Honshu (Japan), but now much less numerous. Rare and declining in Taiwan.
Bibliography. Ali (1977), Ali & Ripley (1974), Brazil (1991), Chae Hee-Young (1997a, 1997b, 1998), Cheng Tsohsin (1987), Clement *et al.* (1993), Dementiev *et al.* (1954, 1970), Fu Tongsheng *et al.* (1998), Haneda & Kumagai (1975), Hartert (1904), Li Dehao *et al.* (1978), Nechaev (1973), Rasmussen & Anderton (2005b), Roberts (1992), Robson (2000), Schäfer (1938), Smythies (1986), Stepanyan (2003), Summers-Smith (1988), Tomek (2002), Vaurie (1972), Whistler & Kinnear (1949), Wu Lirong *et al.* (2004), Yamashina (1961), Zhang Qingxia *et al.* (2003).

8. Pegu Sparrow

Passer flaveolus

French: Moineau flavéole **German**: Gelbbauchsperling **Spanish**: Gorrión Liso
Other common names: Plain-backed/Olive-crowned Sparrow, Pegu House Sparrow

Taxonomy. *Passer flaveolus* Blyth, 1845, Arakan, Myanmar.
Probably evolved from an isolated population of sparrows that was trapped in an unglaciated refugium in Mekong Delta (S Vietnam) during last glaciation of Pleistocene (25,000–15,000 years ago). Monotypic.
Distribution. Myanmar (except N & SW), Thailand, Laos, Cambodia, C & S Vietnam and N Peninsular Malaysia.
Descriptive notes. c. 14 cm; 17–23 g. Male breeding has crown to upper mantle greenish-grey, forehead and side of forecrown yellowish, lores black, crescent-shaped chestnut band behind eye, around rear of yellow ear-coverts and cheek and extending down to side of neck; lower mantle and upper back, scapulars and lesser upperwing-coverts chestnut, lower back to uppertail-coverts greyish-yellow; median upperwing-coverts dull yellowish to olive, greater coverts blackish with broad



pale edges and narrow pale tips; flight-feathers black with narrow yellowish edges; tail dark grey or grey-brown, feathers narrowly edged pale; chin and centre of throat black, side of throat pale yellow; underparts pale yellow, greyer on breast and flanks; iris dark brown; bill black; legs brown to pinkish-brown. Non-breeding male is similar to breeding, but plumage pattern somewhat obscured by pale feather tips, bill horn-coloured. Female has very "clean" appearance, is plain brownish above, with prominent broad buffish supercilium, wing much as male's, chin and throat whitish-yellow to buffish-white, underparts similar to male's, bill light pinkish-horn. Juvenile resembles female. Voice. Main call a loud, clear disyllabic "chirrup", second syllable rather slurred, used by both sexes at nest and roost, similar to "chirrup" call of *P. domesticus*. Threat "chit-chit-chit" or "chi-chi-chip-chip", and alarm "chu chu" or "chu-chu-weet"; these also regularly heard from roost as birds settle for the night.
Habitat. Cultivated areas with trees, plantations and small copses, scrub, and woodland edges; also occurs at edges of areas inhabited by man, where it overlaps with *P. montanus*. Lowlands to at least 1500 m.
Food and Feeding. Predominantly vegetable matter, including seeds of grasses, cultivated cereals and small herbs. Nestlings fed with insects, mainly aphids (Aphidoidea), bugs (Hemiptera) and the caterpillars of Lepidoptera. Collects insects from small outer branches of trees by manoeuvring acrobatically, also by searching on ground. Forages in small groups; in larger flocks in non-breeding season.
Breeding. Season mainly Jan–Jul, but breeding recorded in most months of year; probably two broods. In loose colonies, usually of 5–10 pairs, but occasionally up to 30 pairs. Nest a loosely woven globular structure of grasses, small twigs and rootlets, domed, with entrance on side, lined with feathers, well hidden in branches of tree, or placed in hole in tree or building, or sometimes in cavity in other structure (e.g. lamppost). Clutch 3–4 eggs; young reared by both sexes; no information on duration of incubation and nestling periods.
Movements. Nomadic outside breeding season, wandering to gather at ripening rice paddies.
Status and Conservation. Not globally threatened. Locally common. Formerly more restricted in range; spread S along Malay Peninsula as forest clearance in middle of 20th century created open country suitable for this species.
Bibliography. Clement *et al.* (1993), Lekagul & Round (1991), McClure & Kwanyuen (1973), Medway & Wells (1976), Pantuwatana *et al.* (1969), Robson (2000), Ruelle (1992b), Smythies (1986), Summers-Smith (1981, 1988), Wells (2007), Williamson (1918).

9. Dead Sea Sparrow

Passer moabiticus

French: Moineau de la mer Morte **German**: Moabsperling **Spanish**: Gorrión del Mar Muerto
Other common names: Scrub Sparrow; Afghan Scrub Sparrow, Yates's Sparrow (*yatii*)

Taxonomy. *Passer moabiticus* Tristram, 1864, Israel and Jordan.
Probably evolved from an early sparrow population that was trapped in an ice-free area in Tigris–Euphrates Valley during last glaciation of Pleistocene (25,000–15,000 years ago). E race *yatii* sometimes considered to be a separate species, primarily on grounds of its morphology and geographical separation. Birds in S Turkey, N Syria, Iraq and SW Iran sometimes treated as additional race, *mesopotamicus* (described from SW Iran), but character details appear indistinguishable from those of nominate and published mensural data overlap with those of latter. Two subspecies currently recognized.
Subspecies and Distribution.
P. m. moabiticus Tristram, 1864 – S Turkey, Cyprus, Israel, W Jordan, N Syria and C Iraq E to SW Iran.
P. m yatii Sharpe, 1888 – Seistan region, on borders of E Iran and SW Afghanistan.

Descriptive notes. 12 cm; 14–20 g. Male nominate race breeding has head and nape mainly pale grey, long pale supercilium whitish at front and becoming broader and more buffish behind eye, black lores, white submoustachial stripe, small black bib on chin and throat, pale yellow patch at side of throat; upperparts buff, mantle and back streaked black, scapulars greyer and streaked, rump and uppertail-coverts grey; lesser upperwing-coverts black, tipped white, median and greater coverts chestnut with pale tips, flight-feathers black with broad sandy edges; tail dark brownish with paler edges; underparts greyish-white, greyer on breast, undertail-coverts white with reddish-buff tips; iris dark brown; bill black; legs pale pinkish-brown. Non-breeding male is somewhat duller, plumage pattern obscured by paler feather tips, bill horn-coloured. Female is similar to male but paler and buffish, lacking chestnut colour, with pale buff line on each side of mantle, no black bib, bill yellowish with dark tip. Juvenile resembles female but is less bright, with duller supercilium, no yellow on side of throat. Race *yatii* is paler than nominate, washed yellowish on lower parts. Voice. Noisy at nest-site, otherwise rather quiet. Male nest-ownership call "chip-chip-chip" or "chip-chip-chizz"; this becomes excited "chilling-chillung-chillung" or "tweng-tweng-tweng" (with wings raised and flicked) to attract a female. Both sexes have "chur-it-it-it chit-it-it chitup chittup" alarm associated with tail-flicking. Female uses soft "tweeng tweeng tweeng" as invitation to copulation. Also indulges in "social song" consisting of soft conversational notes when individuals collect in trees between bouts of feeding.
Habitat. Riverine or lacustrine areas with trees or scrub, and irrigated semi-desert where flush of annual grasses. Outside breeding season in cultivated land. Unusually for genus, has no association with built-up areas or habitations.
Food and Feeding. Predominatly a seed eater, specializing on smaller seeds of grasses, rushes and sedges, shrubs and trees. Nestlings fed with both invertebrates and seeds. Searches leaves of trees for insects. Forages also on ground. In loose flocks.
Breeding. Season Mar–Jul; up to three broods. Breeds in loose colonies of 10–100 pairs. Nest a large ovoid structure, mean diameter 30 cm, domed, entrance spiralling down from top, strongly

constructed from dead twigs, lined with feathers and plant down, built openly in branches of tree, frequently dead tree standing in water. Clutch 3–5 eggs; incubation by female only, eggs may be uncovered during heat of day in high-temperature regions, period c. 12 days; chicks fed mainly by female, nestling period 14–15 days.

Movements. Migratory and partially migratory. Leaves breeding areas in autumn, apparently dispersing into more open areas and some withdrawing S. In W of range, recent records suggest S movement in Israel, some reaching NE Egypt (Sinai), and others reported from Eastern Province of Saudi Arabia S to Bahrain and United Arab Emirates, but information on winter distribution in this relatively poorly studied area very scanty. E race *yatii* makes definite S migration to N Baluchistan, in W Pakistan.

Status and Conservation. Not globally threatened. Locally common in W of range; locally common in Afghanistan. Numbers in breeding colonies tend to rise and fall, particularly with changes in land use. Has extended its range since middle of 20th century. First recorded Cyprus in 1973 and bred in dead trees in saline lake near Akrotiri from 1976; became extinct in 1980s when lake dried out, although small numbers considered still to breed on the island.

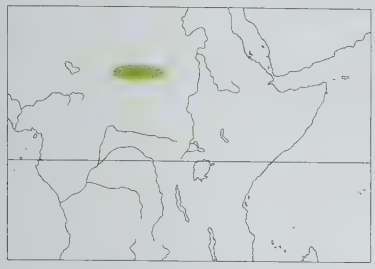
Bibliography. Ali & Ripley (1974), Boros & Horváth (1954), Carruthers (1910a, 1910b, 1949), Christison (1941), Clement *et al.* (1993), Cramp & Perrins (1994), Dickinson (2003), Dijkstra (1992), Hartert (1904), Hirschfeld & Symens (1992), Kirwan (2004), Kirwan *et al.* (2008), Lulav (1967), Marchant (1963), Meinertzhagen (1954), Mendelssohn (1955), Rasmussen & Anderton (2005b), Scott *et al.* (1975), Shirihai (1996), Summers-Smith (1988), Yom-Tov (1980), Yom-Tov & Ar (1980), Yom-Tov, Ar & Mendelssohn (1978), Yom-Tov, Mendelssohn & Ar (1976).

10. Cape Verde Sparrow

Passer iagoensis

French: Moineau du Cap-Vert **German**: Kapverdensperling **Spanish**: Gorrión de Cabo Verde
Other common names: Iago/Rufous-backed Sparrow

Taxonomy. *Pyrgita Iagoensis* Gould, 1838, São Tiago, Cape Verde Islands.
Forms a superspecies with *P. cordofanicus*, *P. shelleyi*, *P. insularis*, *P. rufocinctus* and *P. motitensis*, and all sometimes considered conspecific. Treated as distinct species on grounds mainly of morphological and behavioural differences from others. Monotypic.
Distribution. Cape Verde Is, off W Africa.



Descriptive notes. 12·5–13 cm. Small compact sparrow. Male breeding has forehead, crown and lores blackish, supraloral line whitish, narrow black line behind eye, nape to mantle grey; side of head silvery white, broad rufous-brown band from side of crown behind eye, extending behind ear-coverts and curving down to lower side of neck; scapulars and back chestnut, streaked black, lower back rich brown to chestnut, uppertail-coverts grey (sometimes tinged brown); median upperwing-coverts black with broad white tips, greaters dark brown with paler edges and pale buff-brown tips, flight-feathers blackish, secondaries and tertials edged pale buff-brown, small sandy area at base of primaries; tail dark brown with narrow pale edges; chin and central throat black (small bib); underparts silvery white, greyer on side of breast and flanks; individuals nesting in holes in lava cliffs become noticeably worn through abrasion caused by lava as they regularly enter and leave nest-site; iris dark brown; bill black; legs brown or flesh-brown. Non-breeding male is duller, bill horn-coloured. Female is mostly grey-brown with conspicuous creamy supercilium, pattern of upperparts and wing as for male but duller, lacking chestnut tones, chin and throat white. Juvenile is similar to female, with supercilium sometimes cinnamon and sometimes pale cream (presumably male and female, respectively, though this requires confirmation). Voice. Call of male a twangy "cheesp", "chew-weep" or "chew-leep", used to proclaim nest ownership; notes sometimes strung together into a song, "cheep chirri chip cheep chirri chip cheep". Churring "chur-chur-chur" alarm and a speeded-up version, "chur-it-it-it-it", used by both sexes at nest.
Habitat. Typically in dry lava plains to coastal cliffs, but extending also into cultivated land and built-up areas, where it becomes a complete town bird. Breeds together with *P. domesticus* in Mindelo, the principal town on São Vicente.
Food and Feeding. Mainly seeds of small plants, including grasses and cultivated cereals; also domestic scraps in urban areas. Nestlings fed with caterpillars of Lepidoptera and grasshoppers (Orthoptera). Gregarious; in small groups when breeding, and in larger flocks at other times.
Breeding. Season Sept–Mar, associated with rains. In loose colonies. Nest domed, with entrance at side, constructed from thin plant stems, lined with hair and feathers, mainly in hole in lava cliff, stone wall, building, street light or under boulders, sometimes a free-standing nest, 15 × 25 cm, in branches of tree. Clutch 3–5 eggs; both sexes take part in rearing of young. No information on incubation and fledging periods.
Movements. Mainly sedentary; presumably some dispersal that replenishes populations on smaller islands, which tend to die out and later become re-established.
Status and Conservation. Not globally threatened. Restricted-range species: present in Cape Verde Islands EBA. Common and widespread in its limited range. Sporadic on some of the smaller islands, e.g. Branco, Sal and Santa Luzia; strangely, is absent from Fogo.
Bibliography. 11. Kordofan Rufous Sparrow

Passer cordofanicus

French: Moineau du Kordofan **German**: Kordofansperling **Spanish**: Gorrión del Kordofán
Other common names: Sudan Rufous Sparrow

Taxonomy. *Passer cordofanicus* Heuglin, 1874, Melspez, Kordofan, Sudan.
Forms a superspecies with *P. iagoensis*, *P. shelleyi*, *P. insularis*, *P. rufocinctus* and *P. motitensis*, and all sometimes considered conspecific. Monotypic.
Distribution. E Chad (E from Oum-Hadjer) and W Sudan (Darfur and Kordofan).
Descriptive notes. 13–15 cm. Small sparrow with heavy, slightly arched bill. Male has blue-grey crown and nape, black lores, crescent-shaped chestnut band behind eye and down to side of neck, white cheek separated from crown by narrow black line behind eye and around ear-coverts, small

and narrow black bib; upperparts chestnut, upper back boldly streaked black; upperwing blackish to dark brown, feathers edged buffish, broad white tips on median coverts, narrow buff tips on greater coverts, small buff or sandy patch at base of primaries; tail dark brown, outer feathers edged paler; underparts pure white; iris dark brown; bill horn-coloured, becoming black in breeding season; legs brownish. Distinguished from very similar *P. motitensis* mainly by distinctly smaller size, and white (not pale grey) cheek and underparts. Female is similar to male but paler, with black areas replaced by grey, chestnut on head paler and buffier. Juvenile resembles female, but with paler and washed-out appearance. Voice. Not studied; said not to be distinguishable from that of other sparrows, e.g. *P. motitensis*.

Habitat. Arid country, usually near villages and surrounding cultivated land.

Food and Feeding. Few data. Mainly grain and seeds.

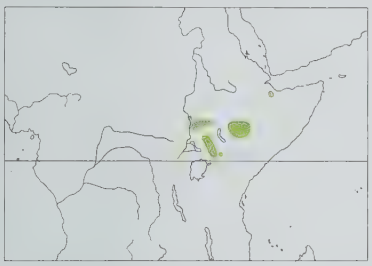
Breeding. Season Jun–Sept in Chad and Sept–Nov in Sudan. Nest an untidy spherical bundle of dry grass, domed and with long entrance tunnel, placed in thorny bush. Clutch 3–5 eggs. No other information.

Movements. No information. Presumed mainly resident.

Status and Conservation. Not globally threatened. Common to locally common within small range.

Bibliography. Cave & Macdonald (1955), Clement *et al.* (1993), Dickinson (2003), Fry & Keith (2004), Grant & Mackworth-Praed (1944a), Hall & Moreau (1970), Lynes (1924), Mackworth-Praed & Grant (1960), Nikolaus (1987), Summers-Smith (1988), White (1963), White & Moreau (1958).

12. White Nile Rufous Sparrow



Passer shelleyi

French: Moineau de Shelley **German**: Nilsperling **Spanish**: Gorrión de Shelley

Taxonomy. *Passer shelleyi* Sharpe, 1891, Lado, southern Sudan.

Forms a superspecies with *P. iagoensis*, *P. cordofanicus*, *P. insularis*, *P. rufocinctus* and *P. motitensis*, and all sometimes considered conspecific. Monotypic.

Distribution. SE Sudan, NE Uganda, W Kenya, S & E Ethiopia and NW Somalia.

Descriptive notes. 13–15 cm. Male has pale blue-grey crown and nape to upper mantle, black lores, crescent-shaped chestnut band and thin black line from behind eye extending to side of neck, grey to dull white ear-coverts and cheek, small and narrow black bib; upperparts posterior to upper mantle pale chestnut, back boldly streaked black; upperwing dark brown to blackish, feathers edged buffish, broad white tips on median coverts, narrow buff tips on greater coverts, small pale patch at base of primaries; tail dark brown, outer feathers edged paler; underparts dusky grey, becoming lighter on belly; iris dark brown; bill horn-coloured, becoming dark slate in breeding season; legs brownish. Differs from similar *P. motitensis* mainly in smaller size and less brightly coloured plumage. Female is like male but duller, with bib dark grey (rather than black), chestnut areas more buffy. Juvenile resembles female, but with paler, washed-out appearance. Voice. Few details. Musical chirps and harsher scratchy calls reported.

Habitat. Mainly open grassy savanna with trees, at 1000–1700 m, extending into semi-desert on the one hand and into light woodland on the other; also, to limited extent, cultivated land and vicinity of habitations, but not penetrating into villages. Does not associate with humans.

Food and Feeding. Little information. Feeds mainly on the ground, presumably on seeds and insects.

Breeding. Sept–Nov and Mar–Jun. Breeds in small colonies. Nest built by both sexes, ovoid in shape, domed, with entrance on side, loosely constructed from dry grasses, lined with feathers, placed 1–2 m above ground in branches of thorny acacia (*Acacia*). Clutch 3–6 eggs, normally 4. No other information.

Movements. No information.

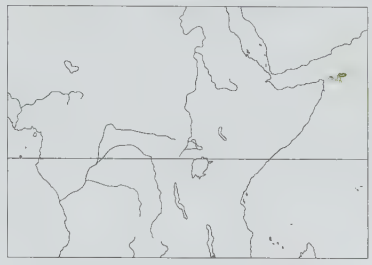
Status and Conservation. Not globally threatened. Moderately common in Ethiopia, fairly common in Uganda, and rare in Kenya; uncommon to rare elsewhere.

Bibliography. Archer & Godman (1961), Ash & Atkins (2009), Benson (1947), Britton (1980), Cave & Macdonald (1955), Clement *et al.* (1993), Dickinson (2003), Fry & Keith (2004), Hall & Moreau (1970), Mackworth-Praed & Grant (1960), Nikolaus (1987), Redman *et al.* (2009), Summers-Smith (1988), White (1963), White & Moreau (1958), Williams & Arlott (1980).

13. Socotra Sparrow

Passer insularis

French: Moineau de Socotra **German**: Sokotrasperling **Spanish**: Gorrión de Socotora
Other common names: Abdelkuri Sparrow (*hemileucus*)



Taxonomy. *Passer insularis* P. L. Sclater and Hartlaub, 1881, Socotra Island.

Forms a superspecies with *P. iagoensis*, *P. cordofanicus*, *P. shelleyi*, *P. rufocinctus* and *P. motitensis*, and all sometimes considered conspecific. It has been suggested that pale race *hemileucus* may represent a full species, apparently genetically divergent from nominate, also that population on islet of Samha might warrant treatment as an additional, small race of present species; further study required. Two subspecies recognized.

Subspecies and Distribution.

P. i. hemileucus Ogilvie-Grant & H. O. Forbes, 1900 – 'Abd al Kuri I (between NE Somalia and Socotra).

P. i. insularis P. L. Sclater & Hartlaub, 1881 – Socotra I, including islets of Samha and Darsa.

Descriptive notes. 13–14 cm; 20–35 g. Male nominate race has forehead to hindneck and entire upperparts grey, prominent black eyestripe, broad rufous-chestnut band from above eye and in crescent around rear of ear-coverts, light greyish ear-coverts and white cheek; back streaked black, prominent chestnut on scapulars; upperwing blackish to dark brown, feathers edged buffish to warm brown, lesser coverts chestnut, broad white tips on median coverts, narrow buff tips on greater coverts, small pale patch at base of primaries; tail dark brown, outer feathers edged paler; chin and throat to upper breast black; underparts greyish; iris dark brown; bill black throughout year; legs brownish. Female is drab brown with greyer upperparts, streaked on back, warm buff supercilium curving down behind ear-coverts, blackish stripe through eye and curving around rear of ear-coverts; bare parts as for male. Juvenile resembles female. Race *hemileucus* is generally paler than nominate, and smaller than birds from Socotra but larger than those from Samha. Voice. Dry chirping calls, "cheep", "chee-cheep", "chip" and "jip"; scolding "jer-jer" and rattling "jajajajajaja" are probably alarm and threat calls.

Habitat. Semi-arid scrub and woodland, also in palm groves, around human settlements, and arid limestone areas; up to 1500 m.

Food and Feeding. Little known. Assumed to take seeds of grasses and small plants (cereals not grown on islands where it lives), but some grain seeds may be available as food for domestic animals. Most water probably obtained from plants (no surface water present on 'Abd al Kuri), but on Socotra freely comes to water put out for camels. Often in flocks of 30–50 individuals.

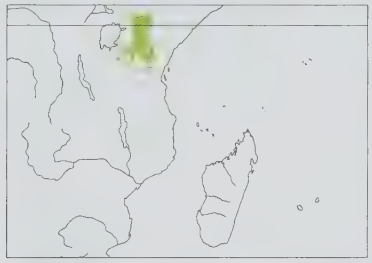
Breeding. Season Nov–Apr; two broods. Breeds in colonies of up to ten pairs; sometimes solitarily. Nest an untidy construction of dead grass, lined with feathers, placed in hole in cliff, house or tree, or openly in branches of thorny tree. Clutch 3 eggs. No other information.

Movements. Resident; some local wandering.

Status and Conservation. Not globally threatened. Restricted-range species: present in Socotra EBA. Abundant on Socotra, where population estimated at c. 250,000 individuals; over 5000 birds on Samha, and over 1000 each on Darsa and 'Abd al Kuri.

Bibliography. Clement *et al.* (1993), Dowsett-& Dowsett-Lemaire (1993), Dymond (1996), Forbes (1903), Fry & Keith (2004), Grant & Mackworth-Praed (1944a), Hall & Moreau (1970), Helbig *et al.* (2002), Kirwan (2008), Kirwan *et al.* (1996), Porter *et al.* (1996), Redman *et al.* (2009), Ripley & Bond (1966), Ryan *et al.* (2008, 2009), Summers-Smith (1988), White (1963), White & Moreau (1958), Wolters (1982).

14. Kenya Rufous Sparrow



Passer rufocinctus

French: Moineau roux **German**: Keniasperling **Spanish**: Gorrión Keniata
Other common names: Rufous Sparrow

Taxonomy. *Passer rufocinctus* G. A. Fischer and Reichenow, 1884, Lake Naivasha, Kenya.

Forms a superspecies with *P. iagoensis*, *P. cordofanicus*, *P. shelleyi*, *P. insularis* and *P. motitensis*, and all sometimes considered conspecific. Monotypic.

Distribution. Rift Valley highlands from C Kenya S to N Tanzania.

Descriptive notes. 13–14 cm; 25–32 g. Male has crown to upper mantle, ear-coverts and cheek blue-grey, lores black, chin and throat black, broad chestnut crescentic band extending from above eye around rear of ear-coverts and on neck side forwards almost to black throat patch; lower mantle to uppertail-coverts rufous-chestnut, streaked black on mantle and upper back; upperwing blackish to dark brown, feathers edged buffish, broad white tips on median coverts, small pale patch at base of primaries; tail dark brown, outer feathers edged paler; underparts greyish; iris pale; bill horn-coloured, becoming dark slate in breeding season; legs brownish. Differs from very similar *P. motitensis* mainly in smaller size, pale eye, greyer face, and more grey on neck and mantle. Female is similar to male but duller, with bib dark grey (rather than black) and chestnut replaced by buff. Juvenile is similar to female, but with paler, washed-out appearance. Voice. Call a loud "chreep", "chuweep" or upward-inflected "cher-weep", deeper than that of *P. domesticus*; used for proclaiming nest-site ownership. Song described as thin, sharp metallic notes often alternating with few lower chirps. Nasal "jewy" or "jerwey" and sharp "tsui" or "tseu-pee" presumably threat and alarm calls, respectively.

Habitat. Dry acacia (*Acacia*) savanna, open wooded country, cultivated land, villages and towns; at 1000–3000 m.

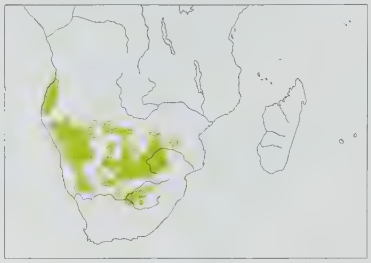
Food and Feeding. Grain, small seeds, domestic scraps; insects fed to unfledged young. Feeds more on ground than does *P. motitensis*. Forages in pairs; sometimes in small groups of up to about ten individuals outside breeding season.

Breeding. Breeds in all months, mainly Apr–Jun and Nov–Dec (coinciding with, respectively, long rains and short rains); possibly two broods. Solitary. Nest built by both sexes, a large, loosely constructed ovoid structure, domed, with entrance on side or near top, mostly of grasses, lined with feathers and animal hair, placed usually in branches of tree, sometimes in more covered site such as creepers on electricity pylon, deserted nest of weaver (Ploceidae) or in thatch of house roof. Clutch 3–5 eggs, occasionally 6. No other information available.

Movements. Resident; some dispersal to lower elevations in non-breeding season.

Status and Conservation. Not globally threatened. Generally common throughout much of its range.

Bibliography. Archer & Godman (1961), Britton (1980), Brown & Britton (1980), Clement *et al.* (1993), Collias & Collias (1964), Dickinson (2003), Friedmann (1937), Fry & Keith (2004), Grant & Mackworth-Praed (1944a), Mackworth-Praed & Grant (1960), Summers-Smith (1988), White (1963), White & Moreau (1958), Williams & Arlott (1980), Zimmerman *et al.* (1996).



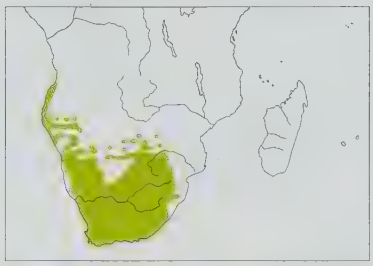
On following page: 15. Southern Rufous Sparrow (*Passer motitensis*); 16. Cape Sparrow (*Passer melanurus*).

15. Southern Rufous Sparrow

Passer motitensis

French: Grand Moineau **German**: Rostsperling **Spanish**: Gorrión Grande
Other common names: Great/Rufous Sparrow; Namibia (Rufous) Sparrow (*benguellensis*)

Taxonomy. *Pyrgita Motitensis* A. Smith, 1836, Hopetown, northern Cape Province; error = Motita, near Old Lakatoo, 135 miles [c. 215 km] north of Orange River, South Africa.
Forms a superspecies with *P. iagoensis*, *P. cordofanicus*, *P. shelleyi*, *P. insularis* and *P. rufocinctus*, and all sometimes considered conspecific. Three subspecies recognized.
Subspecies and Distribution.
P. m. benguellensis Lynes, 1926 – coastal SW Angola and Namibia.
P. m. motitensis (A. Smith, 1836) – Botswana and N South Africa (N Northern Cape and North West Province).
P. m. subsolanus Clancey, 1964 – SW Zimbabwe and N & C South Africa (Limpopo Province S to N & W Free State).



Descriptive notes. 15–16 cm; 26–36 g. One of the largest sparrows, with bill slightly arched. Male nominate race has blue-grey crown and nape, black lores, a crescent-shaped chestnut band (bordered below with trace of black) from eye to side of neck and encircling paler grey ear-coverts, small black bib on chin and central throat; upperparts chestnut, mantle and inner scapulars boldly streaked black; upperwing blackish to dark brown, feathers edged buffish, broad white tips on median coverts, narrower rufous-buff tips on greater coverts, small pale or sandy patch at base of primaries; tail dark brown, outer feathers edged paler; underparts pale grey; iris dark brown; bill horn-coloured, becoming black in breeding season; legs brown or reddish-brown. Female has much the same plumage pattern as male, including small grey bib, but chestnut areas duller, and on head replaced by creamy buff; bill darker than that of other female sparrows. Juvenile resembles female, but has paler, washed-out appearance. Race *benguellensis* is less rufous above and generally paler than nominate; *subsolanus* is more rufous and with heavier streaking above, pale grey below. Voice. Main call a twangy "cheeurr" or "wer-cheerr", fuller and rather deeper in tone than the "chirrup" of *P. domesticus*, given by male to proclaim nest ownership; "cheeurr" and other, similar call notes can be strung together into a song. Partners at nest greet each other with variety of soft conversational notes, "chee-ti-cheet", "ti-cheet-it" or "chee-wee". Fast "churr" in threat; nasal "jwer" to signify alarm.
Habitat. Dry acacia (*Acacia*) savanna, frequenting trees; not associated with man.
Food and Feeding. Seeds of grass and cultivated cereals. Nestling diet is animal food, with caterpillars (Lepidoptera) recorded. Less gregarious than most sparrows; usually in pairs, occasionally in small flocks (e.g. at water-drinking sites).
Breeding. Season Sept–Feb; two broods. Solitary. Nest built by both sexes, free-standing ovoid about the size of a rugby football, domed, with entrance near top at end, constructed mainly from grass, lined with feathers and plant down, placed in branches of thorny tree, occasionally in crevice in rocks. Clutch 3–6 eggs; incubation period 12–14 days; chicks fed by both parents, nestling period 15–18 days.
Movements. Nomadic, with post-breeding dispersal.
Status and Conservation. Not globally threatened. Locally common to uncommon in South Africa; somewhat uncommon elsewhere and generally local. Density in Botswana and N South Africa (N Limpopo Province) 1 pair/100–500 ha (equivalent to 0·2–1 pair/km²).
Bibliography. Clancey (1964b, 1965), Clement *et al.* (1993), Dowsett (2009), Fry & Keith (2004), Grubbe (1990), Hall & Moreau (1970), Harrison *et al.* (1997), Hockey *et al.* (2005), Macdonald (1957), Maclean (1985), Milewski (1975), Milstein (1975), Summers-Smith (1983, 1988), Traylor (1965), White (1963), White & Moreau (1958), Winterbottom (1966).

16. Cape Sparrow

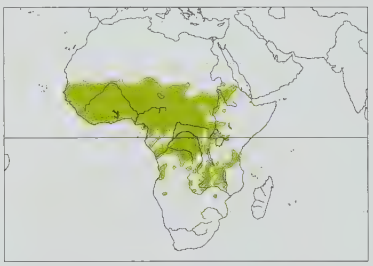
Passer melanurus

French: Moineau mélanure **German**: Kapsperling **Spanish**: Gorrión de El Cabo

Taxonomy. *Loxia melanura* Statius Müller, 1776, Cape Town, South Africa.
Hybridization with *P. domesticus* recorded. Race *vicinus* sometimes subsumed into nominate. Three subspecies currently recognized.
Subspecies and Distribution.
P. m. damarensis Reichenow, 1902 – extreme SW Angola, Namibia, W and E Botswana and extreme W Zimbabwe S to N South Africa (S to Northern Cape, North West Province and N Limpopo Province).
P. m. melanurus (Statius Müller, 1776) – SW South Africa (S Northern Cape and Western Cape E to SW Free State).
P. m. vicinus Clancey, 1958 – E South Africa (S Limpopo Province S to E Free State, W KwaZulu-Natal and Eastern Cape) and Lesotho.

Descriptive notes. 14–16 cm; 17–38 g. Male nominate race has entire head down to upper breast black apart from white crescent-shaped band from eye back to nape and then forward to side of lower throat; upperparts, including scapulars and lesser upperwing-coverts, chestnut, uppertail-coverts grey; upperwing dark brown with warm buffish edges, median coverts tipped white, greater coverts narrowly tipped buffish to off-white, small pale patch at base of primaries; tail dark brown with narrow pale edges; underparts below upper breast greyish on sides, whiter on central abdomen and undertail-coverts; iris dark brown; bill horn-coloured, becoming black in breeding season; legs dark brown to blackish-brown. Female has plumage pattern similar to that of male, but with black replaced by grey and the chestnut areas duller. Juvenile is like female. Race *damarensis* is slightly smaller than nominate, male with black of head tinged brown, female paler; *vicinus* is larger than nominate, male with black more glossy and underparts pure white, female darker. Voice. Call of male at nest a distinctive, loud and far-carrying "tweeng" or "twilleeng", which can change into a jerky, repetitive song with variants of call notes, e.g. "chu chup chiju chip choop chollop chlip chop chrreep", given at rate of two calls per second; much more melodious than familiar "chirrup" call of *P. domesticus*. Has typical sparrow "churr", used in threat; flight call "chui".
Habitat. Semi-arid regions with annual rainfall less than 750 mm, from open savanna with trees to light woodland; also in cultivated land and built-up areas, where it tends to be commoner than in presumed original habitat of grassland savanna. Normally not far from water source.
Food and Feeding. Primarily seeds, specializing on larger seeds of grasses and cultivated cereals; to lesser extent soft shoots and buds of plants, nectar and, in recent years, grapes and other cultivated fruits. Some animal food taken during breeding season, and nestlings fed mainly with caterpillars of Lepidoptera. Takes some insects in flight. Drinks regularly. In small groups and flocks; flocks of up to c. 200 individuals in non-breeding season.
Breeding. In arid regions an opportunist breeder, depending on rains and associated flush of insects; in cultivated regions more regular pattern, breeding mainly Oct–Feb; one or two broods, but up to five in more favoured areas. Mainly social breeder, in loose colonies of 50–100 pairs, a small proportion solitary; extremely territorial. In unusual group display, 20–50 individuals, of both sexes, gather close together on ground, with head held up and tail touching ground, group then moves slowly along, birds hopping at irregular intervals, and one or more fly up and hover over rest of group at height of 30–60 cm; this lasts for 1–4 minutes before individuals gradually disperse; significance of behaviour, whether associated with breeding or merely with social bonding, not known. Nest built by both sexes, a loose, untidy domed structure constructed with coarse dry grass stems and small twigs, lined with feathers and soft plant material, mainly in thorn tree, sometimes on telegraph pole or pylon; nests also in covered site in creepers on wall, or hole in earth bank, haystack or building. Clutch 2–5 eggs; incubation period 12–14 days; chicks fed by both parents, nestling period 16–17 days, but can be as much as 25 days when food availability poor. Breeding success 50–69% in built-up areas, only 25% in agricultural areas; annual productivity estimated at 3·5 young per pair.
Movements. Sedentary cultivated and urban areas; nomadic in more arid areas, settling to breed when conditions favourable.
Status and Conservation. Not globally threatened. Common to locally abundant. Density near Bloemfontein (C South Africa) 152 pairs/100 ha. Has increased in cultivated districts, becoming a pest in wine-growing regions.
Bibliography. Clancey (1958), Clement *et al.* (1993), Dean (1977, 1978a), Earlé (1986, 1988), Fraser *et al.* (1992), Fry & Keith (2004), Harrison *et al.* (1997), Hockey *et al.* (2005), Immelmann (1970), Kopij (1999b), Maclean (1985), Markus (1964, 1965), McFarlane (1997), Meier (1997), Milton & Dean (1999), Rowan (1966), Saayman (1963), Seybold (1982), Siegfried (1973), Slotow & Goodfriend (1996), Slotow *et al.* (1993), Summers-Smith (1988), du Toit (1969), Tree (1966).

PLATE 50 ➤



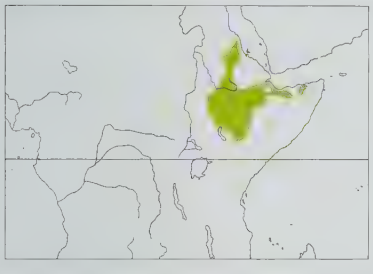
17. Common Grey-headed Sparrow

Passer griseus

French: Moineau gris **German**: Graukopfsperling **Spanish**: Gorrión Gris
Other common names: Northern Grey-headed Sparrow

Taxonomy. *Fringilla grisea* Vieillot, 1817, United States; error = Senegal.
Forms a superspecies with *P. swainsonii*, *P. gongonensis*, *P. suahelicus* and *P. diffusus*; all are often treated as conspecific, but they appear not to interbreed in at least parts of their ranges where geographical overlap occurs. It is suggested that an earlier population of grey-headed sparrows was split into five groups by a pluvial period in Pleistocene; as climate became drier, these five then spread and again came into contact with one another, but by then had become sufficiently distinct to remain separate, partly through minor habitat preferences and morphological differences. Race *mosambicus* of *P. diffusus* considered by some to belong with present species. Three subspecies currently recognized.
Subspecies and Distribution.
P. g. laeneni Niethammer, 1955 – Mali and Burkina Faso E to W Sudan, S to N Cameroon.
P. g. griseus (Vieillot, 1817) – Senegal and S Mauritania E to Ivory Coast and to S Sudan, S to N Gabon and extreme N Central African Republic; also Bioko I (Fernandóo Po).
P. g. ugandae Reichenow, 1904 – N Ethiopia, N Eritrea and SE Sudan S to Angola, extreme N Namibia, Zambia, Malawi, C & NE Tanzania and N & NE Zimbabwe.

Descriptive notes. 14–15 cm; 18–43 g. Nominate race has head and neck ash-grey, mantle and upper back grey-brown, lower back and rump dull chestnut, shoulder cinnamon-red; upperwing-coverts rusty, inner median coverts variably white, flight-feathers black with rusty edgings; tail brown with paler edges; chin and throat white, sharply demarcated from grey underparts, belly to undertail-coverts slightly paler grey; iris brown; bill black to brownish-horn; legs grey-brown or tinged slightly pinkish. Distinguished from most other members of superspecies mainly by sharply defined white throat patch. Sexes alike. Juvenile is like adult, but duller and browner, mantle slightly streaked, no white in wing-coverts, bill horn-coloured. Race *ugandae* is darker than nominate, with head grey-brown, white bib well defined, belly whiter; *laeneni* is much paler, underparts white, bib poorly differentiated. Voice. Call of male at nest a variety of harsh chirps, transcribed variously as "chip", "chirp", "cheerp" or "tyep"; notes can be



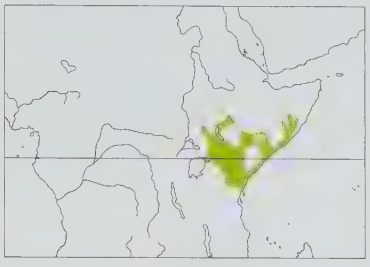
strung together with more liquid ones, such as "twee", to form rather scratchy song. Alarm a dry churring "cher-it-it-it".
Habitat. Commonly associated with cultivation and human habitations, also in grassland savanna and light woodland. Inhabits less arid country than that preferred by others of the superspecies; in areas of overlap with them, is associated more with habitations. Lowlands to 2500 m.
Food and Feeding. Largely granivorous, taking seeds of grasses and cultivated cereals; also small fruits; in urban habitats takes household scraps. Nestlings fed with variety of insects, including weevils (Curculionidae), grasshoppers (Orthoptera), ants (Formicidae) and flying termites (Isoptera). In urban areas, collects insects that have been attracted to lights at night and later lie dead on ground below. In pairs, small groups and flocks; larger gatherings outside breeding season.
Breeding. Breeds in all months of year, coinciding with local rains, but prolonged in areas with irrigated cultivation; normally three broods. Generally in loose colonies; occasionally solitary. Nest built by both sexes, domed, with entrance on side, an untidy accumulation of dead grasses, lined with feathers, placed in tree; nests also in variety of more concealed sites, such as hole in tree or building, hollow steel girder or pipe. Clutch 3–4 eggs, occasionally 2; incubation by female, period c. 16 days; chicks fed by both parents, nestling period c. 19 days.
Movements. Nomadic outside breeding season.
Status and Conservation. Not globally threatened. Common throughout range. Density in Nigeria (S Aïr) reported as 5 birds/ha. Species is currently spreading to E & SE.
Bibliography. Ash & Atkins (2009), Benson (1956), Borrow & Demey (2001), Britton (1980), Chapin (1954), Clancey (1959c), Clement *et al.* (1993), Dickinson (2003), Dowsett *et al.* (2008), Fry & Keith (2004), Gyldenstolpe (1922), Hall & Moreau (1970), Irwin (2002, 2004), Lamm (1959), Mackworth-Praed & Grant (1960, 1973), McCarthy (2006), Nhlane (1993), Nikolaus (1987), Pollard (2002), Redman *et al.* (2009), Ruelle (1992b), Serle & Morel (1977), Summers-Smith (1988), Williams & Arlott (1980).

18. Swainson's Sparrow

Passer swainsonii

French: Moineau de Swainson **German**: Swainsonsperling **Spanish**: Gorrión de Swainson

Taxonomy. *Pyrgita swainsonii* Rüppell, 1840, northern Ethiopia.
Forms a superspecies with *P. griseus*, *P. gongonensis*, *P. suahelicus* and *P. diffusus*; all are often treated as conspecific, but they appear not to interbreed in at least parts of their ranges where geographical overlap occurs. It is suggested that an earlier population of grey-headed sparrows was split into five groups by a pluvial period in Pleistocene; as climate became drier, these five then spread and again came into contact with one another, but by then had become sufficiently distinct to remain separate, partly through minor habitat preferences and morphological differences. Monotypic.
Distribution. Coastal & SE Sudan (S from Port Sudan), Eritrea, Ethiopia, N Somalia and N Kenya.



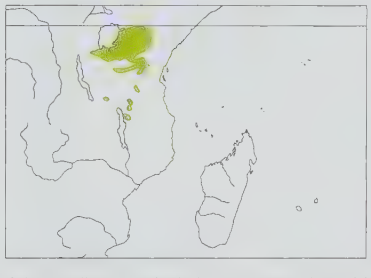
Descriptive notes. 16 cm; 27–35 g. Head, neck and underparts are darkish grey, except for small white patch on belly; indistinct paler patch on throat; mantle and back dull brown, rump chestnut; upperwing brown, except for cinnamon-red on shoulder and narrow white wingbar (tips of median coverts); tail brown; iris brown; bill black; legs grey-brown or tinged slightly pinkish. Differs from very similar *P. griseus* in being larger and darker, lacking clear white throat patch, and white wingbar tends to be more prominent; from *P. gongonensis* in being smaller and less dark, with much smaller white wingbar, smaller bill. Sexes alike. Juvenile is like adult, but lacks white on median coverts, bill paler. Voice. Call of male at nest "chirrip" or "chiri-up", similar to that of *P. griseus* but slightly more musical.
Habitat. Found in all habitats other than dense forest, from open country with bush and scrub to cultivated land, particularly in towns and villages; 1400–4500 m in Ethiopian Highlands, but also at sea-level in N of range, where confined to villages and towns.
Food and Feeding. Mainly seeds of grasses and cultivated cereals, but no detailed study available. Young fed mainly with insects. Forages in pairs and small groups; outside breeding season forms larger loose flocks, at times containing hundreds of individuals.
Breeding. Breeds at all times of year, coinciding with rains in different parts of range. Nest domed, with entrance at side, an untidy bundle of grass, lined with feathers, placed in tree; nests also in variety of enclosed sites, including hole in tree or building, crown of palm, or abandoned nest of other bird, e.g. nests of swallows (Hirundinidae) under house eaves. Clutch 3–6 eggs. No other information.
Movements. Nomadic outside breeding season, flocks roaming in search of food, but no regular pattern of migration.
Status and Conservation. Not globally threatened. Common or fairly common in almost whole of range; uncommon in Sudan. Apparently little current change in numbers.
Bibliography. Archer & Godman (1961), Ash & Atkins (2009), Benson (1947), de Bont (2009), Britton (1980), Cheesman & Sclater (1936), Clement *et al.* (1993), Dickinson (2003), Erlanger (1907), Friedmann (1937), Fry & Keith (2004), Mackworth-Praed & Grant (1960), Redman *et al.* (2009), Smith (1957), Stevenson & Fanshawe (2002), Summers-Smith (1988), Urban & Boswall (1969).

19. Parrot-billed Sparrow

Passer gongonensis

French: Moineau perroquet **German**: Papageischnabelsperling **Spanish**: Gorrión Picogordo

Taxonomy. *Pseudostruthus gongonensis* Oustalet, 1890, Gongoni, near Mombasa, Kenya.
Forms a superspecies with *P. griseus*, *P. swainsonii*, *P. suahelicus* and *P. diffusus*; all are often treated as conspecific, but they appear not to interbreed in at least parts of their ranges where geographical overlap occurs. It is suggested that an earlier population of grey-headed sparrows was split into five groups by a pluvial period in Pleistocene; as climate became drier, these five then spread and again came into contact with one another, but by then had become sufficiently distinct to remain separate, partly through minor habitat preferences and morphological differences. Monotypic.
Distribution. Extreme SE Sudan, S Ethiopia, S Somalia, extreme E Uganda, most of Kenya, and extreme NE Tanzania.



Descriptive notes. 18 cm; 33·5–48 g. The largest of the African grey-headed sparrows; distinctive heavy arched bill gives "Roman-nosed" appearance. Head, neck and underparts are mid-grey; upperparts, including tail and upperwing, brown, rump bright chestnut; upperwing-coverts bright chestnut, conspicuous white patch formed by white tips of median coverts, flight-feathers edged chestnut; iris brown; bill black; legs pale brown or pale flesh-brown. Differs from other members of superspecies in larger size, generally darker appearance, on normally more extensive wingbar. Sexes alike. Juvenile is browner than adult, lacks white wingbar, bill horn-coloured. Voice. Call "choop", can be combined in a series of similar notes to produce a song, "choop chyop choop chup chop choop", deeper in tone than those of other African grey-headed sparrows. Churring "chrrrrrrryek" presumed to be an alarm call.
Habitat. Open country and bush, extending into light woodland; in more arid country than that in which other members of the superspecies found. Infrequently seen around villages and built-up areas, although comes to regular picnic sites in game parks.
Food and Feeding. Mainly a seed-eater; recently recorded as taking bread and other scraps from the ground at lodges and picnic sites. Nestling diet not recorded, presumed to be mainly insects. Forages in pairs and small groups, rarely in larger flocks.
Breeding. Throughout year in different parts of range, breeding coinciding with rains, but also in dry season where irrigated cultivation. Nest an untidy mass of dry grass, domed, with entrance at side, lined with feathers, built in branches of tree, occasionally in hole in baobab (*Adansonia*); old nest of other species sometimes used. Clutch 2 eggs in Kenya, 4–5 in Somalia. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. Common in most of range; uncommon in Sudan. Numbers apparently stable.
Bibliography. Ash & Atkins (2009), Benson (1947), Britton (1980), Clement *et al.* (1993), Dickinson (2003), Friedmann (1937), Fry & Keith (2004), Mackworth-Praed & Grant (1960), McCarthy (2006), Ruelle (1992b), Summers-Smith (1988), Williams & Arlott (1980), Zimmerman *et al.* (1996).

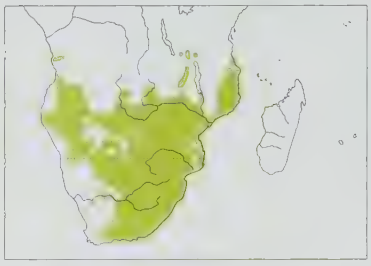
20. Swahili Sparrow

Passer suahelicus

French: Moineau swahili **German**: Suahelisperling **Spanish**: Gorrión Swahili

Taxonomy. *Passer griseus suahelicus* Reichenow, 1904, Bussissi, Mwanza district, northern Tanzania.
Forms a superspecies with *P. griseus*, *P. swainsonii*, *P. gongonensis* and *P. diffusus*; all are often treated as conspecific, but they appear not to interbreed in at least parts of their ranges where geographical overlap occurs. It is suggested that an earlier population of grey-headed sparrows was split into five groups by a pluvial period in Pleistocene; as climate became drier, these five then spread and again came into contact with one another, but by then had become sufficiently distinct to remain separate, partly through minor habitat preferences and morphological differences. Monotypic.
Distribution. S Kenya and N Tanzania S, patchily, to SW Tanzania.

Descriptive notes. 15–16 cm; 20–30 g. Head and neck to back and underparts are greyish-brown, rump chestnut-red; upperwing and tail brown, chestnut-red shoulder, white tips of median upperwing-coverts (rather small wingbar); sometimes paler greyish area on throat; iris brown; bill blackish-horn; legs pale brown or pale flesh-brown. Sexes alike. Juvenile is very similar to adult, but lacks white on median coverts. Voice. Song described as a varied medley of soft calls, e.g. "chup chu-weew chop wor chu-weet chip choy chaw-chip chaw wor-chip chwoop".
Habitat. Grassland with scattered trees and light woodland, particularly near water, also cultivated land and habitations. To 2000 m.
Food and Feeding. Few data. Mainly seeds; also takes scraps near villages, and around lodges of game parks.
Breeding. Jan–May, apparently coinciding with rains. Nest an untidy domed structure, tunnel entrance at side, placed in hole in tree or house, sometimes in tree; old nest of swallow (Hirundinidae) also used. No other information.
Movements. Resident; local movements during rains.
Status and Conservation. Not globally threatened. Generally common. Poorly known species; requires study.
Bibliography. Britton (1980), Clement *et al.* (1993), Fry & Keith (2004), Grant & Mackworth-Praed (1944a), Mackworth-Praed & Grant (1960), McCarthy (2006), Ruelle (1993), Schmidl (1982), Summers-Smith (1988), Zimmerman *et al.* (1996).



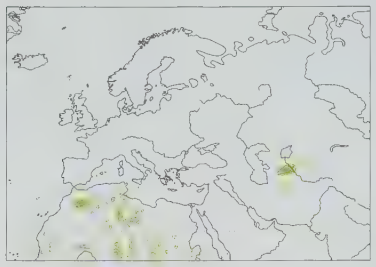
21. Southern Grey-headed Sparrow

Passer diffusus

French: Moineau sud-africain **German**: Damarasperling **Spanish**: Gorrión Sudafricano
Other common names: Cape Sparrow(!)

On following pages: 22. Desert Sparrow (*Passer simplex*); 23. Eurasian Tree Sparrow (*Passer montanus*); 24. Sudan Golden Sparrow (*Passer luteus*); 25. Arabian Golden Sparrow (*Passer euchlorus*); 26. Chestnut Sparrow (*Passer eminibey*).

Taxonomy. *Pyrgita diffusa* A. Smith, 1836, "North of the Orange river" = near Kuruman, Cape Province, South Africa.
Forms a superspecies with *P. griseus*, *P. swainsonii*, *P. gongonensis* and *P. suahelicus*; all are often treated as conspecific, but they appear not to interbreed in at least parts of their ranges where geographical overlap occurs. It is suggested that an earlier population of grey-headed sparrows was split into five groups by a pluvial period in Pleistocene; as climate became drier, these five then spread and again came into contact with one another, but by then had become sufficiently distinct to remain separate, partly through minor habitat preferences and morphological differences. Race *mosambicus* sometimes considered to belong with *P. griseus*, and *stygiceps* sometimes believed to represent darker end of cline in plumage coloration of nominate or possibly a hybrid between nominate race of present species and race *ugandae* of *P. griseus*; further study in area of overlap between the two species required in order to resolve extent to which these taxa are isolated and extent to which they intergrade. Four subspecies currently recognized.
Subspecies and Distribution.
P. d. diffusus (A. Smith, 1836) – W & S Angola E to SW & S Zambia, S to Namibia (except SW), Botswana, W Zimbabwe and W South Africa (except much of SW).
P. d. luangwae Benson, 1956 – upper Luangwa Valley, in E Zambia.
P. d. mosambicus van Someren, 1921 – SE Tanzania and N Mozambique.
P. d. stygiceps Clancey, 1954 – SE Zambia, S Malawi, N & E Zimbabwe, C & S Mozambique, NE & E South Africa, Swaziland and Lesotho.



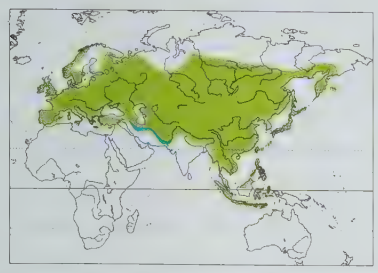
Descriptive notes. 15–16 cm; 20–29·6 g. Nominate race has head and nape pale ash-grey, often with brownish tinge, underparts pale grey, becoming whitish on belly and vent; throat sometimes paler grey than breast (but rarely distinct patch); upperparts, including upperwing, brown, lower back and rump brighter, more chestnut, shoulder and wing-coverts tinged rufous, conspicuous white wingbar formed by white tips of median coverts; tail dark brown; iris dark brown; bill dark brownish-horn, becoming black in breeding season; legs pale pinkish-brown. Sexes alike. Juvenile is similar to adult, but browner, faintly streaked above, and wingbar reduced or absent. Race *luangwae* is smaller than nominate, with finer bill, and warmer chestnut above; *mosambicus* has greyer crown and slightly warmer back; *stygiceps* is browner on upperparts and darker below. Voice. Call a repeated "chirp" or "chirrup", rather softer and more melodious than that of *P. domesticus*. Song a series of rather similar chirping notes strung together, e.g. "chyup chet chyew chyurp chip chyit chooy". Threat a churring "churrrrrdididit" (uttered with wings held out, tail fanned and slightly raised, rump feathers fluffed).
Habitat. Open acacia (*Acacia*) woodland, frequently near settlements, and penetrates into built-up areas; in N part of range occupies drier habitat, and is almost completely associated with mopane (*Colophospermum mopane*) woodland and less with cultivation and settlements.
Food and Feeding. Weed seeds and insects, also buds, berries and nectar; also scraps discarded by humans. Young fed mainly with insects, such as termites (Isoptera). Collects most food from the ground, but otherwise spends much of its time in trees. Forages in pairs and in small flocks. Unusual among *Passer* in that it walks as well as hops.
Breeding. Breeds in all months of year, coinciding with local rains; two broods. Mainly solitary, occasionally in loose colonies. Nest built by both sexes, made from dry grass, lined with feathers, placed mainly in hole in tree or building, often quite small cavity (material completely fills cavity); old nests of other species frequently used; competes for nest-sites with *P. domesticus*. Clutch 2–5 eggs, mostly 3–4; incubation by both sexes, no information on duration of period; chicks fed by both parents, nestling period 16–25 days; fledglings fed by both parents.
Movements. Mainly sedentary; reports of large concentrations suggest local movement. Recent expansion of range indicates some dispersal, presumably by young.
Status and Conservation. Not globally threatened. Common and widespread over most of relatively large range. Density in Swaziland 51 birds/100 ha. Has expanded its range since 1950s; in South Africa, significant extension W into Western Cape, but still absent from more arid Karoo.
Bibliography. Barry (2001), Benson (1956), Bridgeford (2003), Clancey (1959d), Clement *et al.* (1993), Craig *et al.* (1987), Dickinson (2003), Dowsett & Dowsett-Lemaire (1980, 1993), Dowsett *et al.* (2008), Fry & Keith (2004), Goodfellow (1966), Hines (1997), Irwin (2001, 2002), Jones, J.M.B. (2002), Maclean (1985), Markus (1967), Martin *et al.* (1987), McCarthy (2006), Oatley & Skead (1972), Pollard (2002), Summers-Smith (1988), Steyn (2000), Teschemaker (1910), Tree (1972), Ward *et al.* (2004).

22. Desert Sparrow

Passer simplex

French: Moineau blanc **German**: Wüstensperling **Spanish**: Gorrión Sahariano
Other common names: African Desert/White Sparrow

Taxonomy. *Fringilla simplex* M. H. C. Lichtenstein, 1823, Ambukol, Dongola, Sudan.
Sometimes thought, with little justification, to be part of superspecies formed by *P. domesticus*, *P. italiae* and *P. hispaniolensis*. Has been suggested that Asian and African populations might have evolved separately from *P. domesticus*, but it seems more likely that present species once had more continuous distribution (from N Africa E to W Turkestan) until probably up to 50,000 years ago, at least, but has become extinct in C regions with increased aridification. Race *zarudnyi* distinctive, and may represent a separate species. Birds in Mauritania, currently included within nominate, possibly belong to race *saharae*. Three subspecies recognized.
Subspecies and Distribution.
P. s. saharae Erlanger, 1899 – NW Sahara Desert E to W Libya, S at least to S Algeria (Ahaggar) and Chad.
P. s. simplex (M. H. C. Lichtenstein, 1823) – S Sahara from Mauritania and Mali E to S Egypt and Sudan.
P. s. zarudnyi Pleske, 1896 – Turkmenistan and W Uzbekistan.
Descriptive notes. 14–15 cm; 18–21 g. Pale, long-legged sparrow with characteristic upright posture. Male nominate race is pale grey above, sometimes with faint sandy tinge, ear-coverts and cheek white, lores black, extensive black bib from chin to upper breast; lesser upperwing-coverts same as back, median coverts white, greater coverts black with broad white tips, alula and primary coverts mostly black, flight-feathers blackish with pale grey to whitish edges, small white patch at base of primaries (often concealed); tail blackish, feathers edged white, central rectrices tipped white; underparts whitish-buff; iris brown; bill horn-coloured, becoming black in breeding season; legs pale pinkish or pinkish-brown. Female is a nondescript pale sandy or sandy-buff colour, paler below, and lacking any distinct features; wing much as male's, but dark areas paler and more sandy brown. Juvenile resembles female. Race *saharae* is larger and paler than nominate; *zarudnyi* has shorter wing and bill and longer tail, generally plainer and greyer, whiter below without marked buffish tinge, female similar to male in plumage but with grey often slightly tinged buff, and black on head and bib reduced and browner. Voice. Call harsh "tchip" or slightly rolled "chrip" or "drip". Song a high-pitched, shrill "tyi" or "tyi-tyit", alternating with downslurred "tyaa" or "tween", sometimes in 5-note phrase, e.g. "tyi tyi tyi tyi tweeuw", has been described as similar to that of White Wagtail (*Motacilla alba*). In flight a quiet twitter, similar to that of European Greenfinch (*Carduelis chloris*). Threat call a guttural chattering "chit-it-it".



Habitat. Arid sandy areas with scattered trees and bushes. In Africa frequents oases and shrubby growth in wadis and inhabited areas; in Asia confined to bare, rocky areas with sparse trees and bushes.
Food and Feeding. Mainly seeds of desert bushes and ground vegetation, grass seeds, including those of cultivated cereals. Nestlings fed with beetles (Coleoptera), grasshoppers (Orthoptera), Lepidoptera larvae and spiders (Araneae). Takes a higher proportion of animal matter than do other sparrows (shorter alimentary tract compared with that of congeners). Probably obtains all of its water from food. Collects most of food on ground, but spends most of its time in trees. Forages in pairs and small groups; also in small flocks outside breeding season.
Breeding. Season Mar–Aug; two broods. Breeds solitarily or in small colonies, four or five nests in one tree. Nest built by both sexes, domed, with entrance sloping up to nest cup, an irregular mass of dry grass and small twigs, lined with soft plant material and feathers, placed in branches of tree, e.g. acacia (*Acacia*), or in base of large nest of crow (Corvidae) or bird of prey, in Africa more often in hole in tree, wall or deserted building. Clutch 2–6 eggs; incubation by both sexes, period 12–13 days; chicks fed by both parents, nestling period 12–14 days.
Movements. Erratic, at times common in some areas and rare or absent in others; in Asia (race *zarudnyi*), possibly some tendency for withdrawal to S in winter months.
Status and Conservation. Not globally threatened. Locally common; rare in E of range. Erratic use of different nesting areas makes it difficult to know if populations stable or decreasing; this emphasized by recent rediscovery of species in region of type locality, in N Sudan, where it was thought to have become extinct. In Sahara, tends to abandon a locality after having bred there for some years, and to appear in entirely new one. Race *zarudnyi* of C Asia similarly unpredictable, but seems much less secure, with anecdotal information suggesting possible decline and range-contraction; red-listed in Turkmenistan; formerly occurred in the Dasht-e-Lut (Great Salt Desert), in E Iran, but now extinct there. Can cause damage to cereal crops.
Bibliography. Ash & Nikolaus (1991), Borrow & Demey (2001), Clement *et al.* (1993), Cramp & Perrins (1994), Dementiev *et al.* (1954, 1970), Densley (1990a), Dickinson (2003), Fry & Keith (2004), Hartert (1904), Heim de Balsac (1929), Hüe & Etchécopar (1970), Ivanitskii (1997), Kirwan *et al.* (2009), Knystautas (1993), Nikolaus (1987), Ponomareva (1983), Redman (1993), Rustamov & Sopyev (1990), Scott *et al.* (1975), Sopyev (1965), Stepanyan (2003), Summers-Smith (1988), Thévenot *et al.* (2003).

23. Eurasian Tree Sparrow

Passer montanus

French: Moineau friquet **German**: Feldsperling **Spanish**: Gorrión Molinero
Other common names: (European) Tree Sparrow

Taxonomy. *Fringilla montana* Linnaeus, 1758, "in Europa" = northern Italy.
Probably evolved from a sparrow population that was isolated in Yellow R valley (China), which remained free of ice, during last glaciation of Pleistocene (25,000–15,000 years ago). Not infrequently hybridizes with *P. domesticus* where one of the two species is rare and presumably has difficulty in finding mate of own species; hybrids with *P. hispaniolensis* also reported. Race *iubilaeus* is sometimes treated as synonym of *saturatus* and *obscuratus* as synonym of *dilutus*. Proposed race *zaissanensis* (from Kara Irtysh, in extreme E Kazakhstan) subsumed into *dilutus*, and *hepaticus* (from Mishmi Hills, in NW Asssam, in NE India) synonymized with *malaccensis*. Ten subspecies recognized.
Subspecies and Distribution.
P. m. montanus (Linnaeus, 1758) – from Europe E through NC Asia to Kamchatka and Commander Is, S to Mediterranean islands, Turkey, N Kazakhstan, NE Mongolia and NE China (N Inner Mongolia).
P. m. transcaucasicus Buturlin, 1906 – E Asia Minor and Caucasus region S to Armenia and E to N Iran (N of Elburz Mts).
P. m. dilutus Richmond, 1896 – Caspian Sea E to S Kazakhstan, NW China and W & S Mongolia.
P. m. kansuensis Stresemann, 1932 – N Gansu and Tsaidam Basin, in N China.
P. m. tibetanus Stuart Baker, 1925 – S & E Tibetan Plateau and C China (E to SE Qinghai and W Sichuan).
P. m. dybowskii Domaniewski, 1915 – E Asia from extreme SE Russia (lower R Amur) S to NE China (E Inner Mongolia and Liaoning) and N Korea.
P. m. iubilaeus Reichenow, 1907 – E China from Beijing S to E Sichuan and lower R Yangtze.
P. m. obscuratus Jacobi, 1923 – Nepal E to NE India.
P. m. malaccensis A. J. C. Dubois, 1885 – SE Asia from Myanmar E to Indochina and SE China (including Hainan), S to Malay Peninsula, Sumatra, Java, S Philippines, Sulawesi and Lesser Sundas.
P. m. saturatus Stejneger, 1885 – Sakhalin I, S Kurils, Japan, S Korea, Ryukyu Is, Taiwan, Philippines, N Borneo and N Indonesian islands.
Introduced (nominate race) in E USA, where now found in extreme EC Missouri and WC Illinois; also (probably *malaccensis*) in SE Australia, where now present SE Victoria and SE New South Wales (N to about Sydney).
Descriptive notes. 14–15 cm; 17–30 g. A small, neat-looking sparrow, unusual among the black-bibbed species in that sexes are virtually indistinguishable in the field. Nominate race has crown to nape chocolate-brown, ear-coverts and cheek white with prominent black patch, white extending across hindneck (giving white-collared appearance); black lores, black chin and central throat; upperparts yellowish-brown, mantle boldly streaked with black; tips of median and greater upperwing-coverts white (conspicuous double white wingbar); tail grey-brown, narrowly edged buffish; underparts off-white, flanks washed buffish; iris dark brown; bill blackish-horn, becoming black in breeding season; legs pale brown or pale pinkish-brown. Sexes alike. Juvenile is similar to adult, but duller. Races differ mainly in plumage tones, to lesser extent in size, those in more arid regions of Asia tend to be paler than nominate, those in tropical humid areas of SE darker (largest

birds occur at high altitudes, those from SE are smallest): *transcaucasicus* is less bright above and paler below than nominate; *dilutus* is palest race, more sandy in colour on upperparts; *kansuensis* is intermediate in colour between previous and *iubilaeus*; *tibetanus* is much larger than all others; *dybowskii* is distinguished by combination of dark plumage and small bill; *iubilaeus* is rather dark; *obscuratus* is intermediate between preceding race and *saturatus*; *saturatus* is darker and more richly coloured, bill larger than other races; *malaccensis* is similar to last but smaller, often with heavier streaking above. Voice. Basic call "chip", higher-pitched and quite distinct from similar call of *P. domesticus* (in sonagram shown to be disyllabic, as are calls of most of the sparrows, but this cannot be distinguished by ear in field), used by male to proclaim nest ownership, and elaborated into string of similar calls, e.g. "chip chip chicki, chip che chit, chippa-chippa chip", to form a song used for attracting a mate. Rhythmic series of soft calls ("social singing") given from deep cover by flock-members during rest period between feeding bouts. Threat call "tet-tet" or "trr"; alarm harsh, loud single or double "tät", but in mixed-species feeding flocks remains silent and relies on alarm calls of the other species. A series of soft calls is used between mates and between adult and young.

Habitat. In W of range (Britain) mainly in cultivated areas with hedgerow trees, orchards, gardens and farmyards, less commonly in light woodland; to the E is found increasingly not only in built-up areas, but also in open arid country. In Far East, where *P. domesticus* absent, common in built-up areas, occurring even in urban centres; occurs together with *P. domesticus* in Mongolia. In Europe seldom above 1500 m; reaches 4400 m in Asia.

Food and Feeding. Predominantly a seed-eater, preferring smaller seeds of low herbs and grasses, including cultivated cereals; also a significant proportion of animal food, particularly during breeding season. Nestling diet predominantly of insects and spiders (Araneae); mainly aphids (Aphidoidea) when chicks small, but also caterpillars (Lepidoptera), grasshoppers (Orthoptera) and beetles (Coleoptera), particularly weevils (Curculionidae). Bill length increases in summer, when higher proportion of soft insects in the diet (replacing hard seeds, which cause greater wear). Forages in pairs and in small groups; also in larger flocks in non-breeding season.

Breeding. Start of season depends on latitude, ranging from Apr or May in N of range to Jan in extreme S of Asia; up to four broods. Loosely colonial; also solitary. Nest built by both sexes, of dried grass and rootlets, lined with feathers and animal fur, domed (even when in a hole), with entrance on side, mostly in hole in tree, earth bank, cliff or artificial structure, sometimes in base of large nest of heron (Ardeidae), crow (Corvidae) or bird of prey; less frequently free-standing nest in tree, but then usually hidden in thick conifer or creepers. Clutch 2–7 eggs; incubation by both sexes, period 11–14 days; chicks fed by both parents, nestling period 15–20 days (the longer period being for young in nests in stone walls of wells, which have a difficult first flight); tends to be very secretive during breeding, slipping quietly off nest at approach of observer. Success among W European populations 45–75%. Breeding adults survive for average of two seasons, only rarely up to four seasons.

Movements. Mainly sedentary and partially migratory; small amount of dispersal, particularly of juveniles after breeding season. Minor proportion of population in Europe undertakes post-breeding migration S, but this of limited extent and seldom greater than 300 km. More pronounced movements in C Asia, with many migrating through Tien Shan passes and withdrawing S of breeding range. Birds in extreme N of range withdraw to S, and those living in countryside tend to move into built-up areas.

Status and Conservation. Not globally threatened. Widespread and locally numerous. Breeding densities in C Europe range from 10–40 birds/ha in open deciduous woodland to maximum of 3 birds/ha in built-up areas. Estimated European total in 1990s c. 15,000,000 breeding pairs. Population in Britain has fluctuated from a high of c. 1,500,000 individuals in late 1960s to c. 300,000 in 2002. Rough estimates for other European countries include Finland 10,000 birds (1989), Sweden 3,000,000 birds (1976), Netherlands 1,000,000–1,500,000 birds (1975), Germany 1,000,000–1,600,000 birds (2005), Belgium 420,000 birds (1968), France 200,000–2,000,000 birds (1976), Ireland 13,000–15,000 birds (1989). Has been expanding at limits of range, to N in Fennoscandia and to S in both S Europe and SE Asia; colonized Corsica, Sardinia and Malta in 20th century, recently colonized Gran Canaria, in Canary Is, and in last 100 years has spread S in Asia into Sumatra and Java, Borneo, Philippines and S Indonesia, these extensions probably partly aided by introductions. In contrast, there has been a significant decrease in numbers in Britain since 1980s, and in 1996 the species was placed on UK Red List of Species of National Conservation Concern, although some recovery recorded in early years of 21st century, with movement into farm buildings abandoned by *P. domesticus*; similar decline noted in Japan in late years of 20th century. Was perceived as a pest in China, and in 1958 a three-day campaign significantly reduced its numbers (an estimated 800,000 individuals killed in Beijing area alone), but this did not have desired effect of increasing rice harvest; campaign was abandoned, and the species quickly recovered its numbers. Nominate race was introduced in 1870 in St Louis (Missouri), in USA, from where it spread along Mississippi R into Illinois and now occupies area of 22,000 km² in extreme EC Missouri and WC Illinois; introduced (probably race *malaccensis*) in second half of 19th century in Melbourne, in SE Australia, from where spread to SE of Victoria and into New South Wales (N to about Sydney). Attempted introductions in New Zealand and Bermuda apparently unsuccessful. Possible introductions elsewhere.

Bibliography. 24. Sudan Golden Sparrow

Passer luteus

French: Moineau doré **German**: Braunrücken-Goldsperling **Spanish**: Gorrión Dorado
Other common names: Golden Sparrow

Taxonomy. *Fringilla luteus* M. H. C. Lichtenstein, 1823, Dongola, northern Sudan.

This species and *P. euchlorus* formerly placed in a separate genus, *Auripasser*. The two form a superspecies and in the past were often treated as conspecific; some authorities include *P. eminibey* in this superspecies, but this appears not to be justified. Monotypic.

Distribution. Narrow zone in Sahel zone from Mauritania and N Senegal E to Red Sea coast of Sudan.

Descriptive notes. 12–13 cm; 11–16 g. Male has golden-yellow head and underparts, often grey feather tips on ear-coverts; mantle, scapulars and back chestnut, rump yellowish-grey; median and outer greater upperwing-coverts black, tipped white (prominent double wingbar), inner greater coverts mostly chestnut, flight-feathers blackish, edged warm brown to rufous, small pale patch at base of primaries; tail brown, feathers edged paler; iris dark brown; bill horn-coloured, becoming black in breeding season; legs flesh-pink or pinkish-brown. Female has top of head and upperparts sandy brown, face and underparts pale creamy yellow, pale yellowish-buff supercilium, wing like that of male but browner, wingbars dull buff. Juvenile is similar to female, but with grey flecks on back of head and nape, and lighter below; first-year male paler than adult. Voice. Call of male at nest a disyllabic "chitta". Song a high-pitched chittering containing up to 20 notes; at large colonies, song of males loud enough to be heard over engine noise when observer driving past in a car. Twittering flight call resembles that of a cardueline finch. Threat a long drawn-out rattle or "churr"; female invites copulation with soft "dee"; chicks beg with quiet "dipp".

Habitat. Arid sandy savannas with low density of trees and shrubs, and with seasonal ground cover of low annual plants.

Food and Feeding. Primarily seeds of grasses and the smaller seeds of cultivated cereals such as millet; small amount of animal matter. Nestlings fed with invertebrates, including bugs (Hemiptera), caterpillars of Lepidoptera, weevils (Curculionidae) and locust larvae (Acrididae). Gregarious; in large flocks, often with other species, e.g. weavers (Ploceidae).

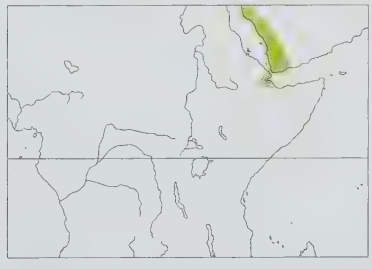
Breeding. Breeding opportunistic, coinciding with rains; one or two broods. Highly colonial; in dispersed colonies of up to 65,000 nests, with densities of 20–570 nests/ha; single large tree can hold up to 30 nests. Nest built by both sexes, with stiff dead twigs woven into branches of tree, side entrance spiralling down to nest-chamber, placed in thorny tree where emergent ground vegetation present; for second brood, builds new nest at new site where conditions favourable, but not known if partners remain together to breed there. Clutch 3–4 eggs; incubation by both sexes, period 10–12 days; chicks fed by both parents, nestling period 13–14 days (suited to short periods when flush of insects persists).

Movements. Highly nomadic, occurrence coinciding with ripening of seeds, but less so in areas where irrigation and cultivation practised. Outside breeding season occurs in small numbers S of breeding range, e.g. in Gambia.

Status and Conservation. Not globally threatened. Common to locally abundant. Breeding range normally lies between 100 mm and 500 mm isohyets (rainfall contours), but in irrigated areas also below the 100 mm limit; for example, has spread N into extreme S Algeria (I-n-Guezzam), presumably because of irrigated farming in area. During the Sahelian drought, which began c. 1968 and lasted for c. 14 years, breeding range shifted S (following the drift of the limiting isohyets). Can become a pest species in cultivated cereals, but, despite extensive control operations, maintains its numbers. In studies in Niger in 1980s, however, this species was found not to damage rice fields, because it preferred to take seeds from ground; moreover, it consumes injurious insects and feeds nestlings with locusts, and should therefore not be considered a pest, although it can have small adverse impact locally.

Bibliography. Ash & Atkins (2009), Borrow & Demey (2001), Bruggers & Bortoli (1976), Clement *et al.* (1993), Cramp & Perrins (1994), Fry & Keith (2004), Jacob & de Schaetzen (1984), Jones (1976), Klein (1988, 1989, 1992), Kunkel (1961), McCarthy (2006), Morel & Morel (1973a, 1973b, 1976, 1978), Neunzig (1928), Nikolaus (1987), Oubron (1967), Redman *et al.* (2009), Ruelle & Semaille (1982), Summers-Smith (1988).

25. Arabian Golden Sparrow



Passer euchlorus

French: Moineau d'Arabie **German**: Jemengoldsperling **Spanish**: Gorrión Árabe

Taxonomy. *Auripasser euchlorus* Bonaparte, 1850, "Abyssinia, Arabia" = Kunfuda, Arabia.

This species and *P. luteus* formerly placed in a separate genus, *Auripasser*. The two form a superspecies and in the past were often treated as conspecific; some authorities include *P. eminibey* in this superspecies, but this appears not to be justified. Monotypic.

Distribution. SW tip of Arabian Peninsula, and Djibouti and extreme coastal NW Somalia.

Descriptive notes. 12–13 cm; 12–17 g. Male is golden-yellow, except for paler yellow upperwing-coverts with greyish inner webs, black flight-feathers with whitish edges, small white patch at base of primaries, black tail feathers broadly edged white; iris dark brown; bill flesh-coloured to creamy grey, becoming black in breeding season; legs pale pinkish-brown. Female is mainly pale buff or sandy grey, pale lemon-buff below; with wing and tail similar to male's. Juvenile is similar to female, but with faint spotting on upperparts. Voice. Soft, disyllabic, high-pitched chirp, similar to that of *P. luteus*. Flocks utter continuous soft twittering.

Habitat. Arid thornbush savanna and nearby cultivated land.

Food and Feeding. Seeds of grasses and cultivated cereals, especially millet; little recorded. Highly gregarious, forages in small flocks; larger flocks, sometimes of thousands, in non-breeding season.

Breeding. Breeding probably associated with rains, recorded in Mar–Jul in Yemen and Mar–May in Djibouti. Highly colonial, with 20–30 nests in one tree. Nest a compact oval structure, domed, with entrance on side, made from thin acacia (*Acacia*) twigs, lined with plant fibres and feathers, placed 2–3 m above ground in tree, typically acacia, with nest worked into the branches. Clutch 4–6 eggs; incubation by female, chicks fed by both sexes; no information on duration of incubation and nestling periods.

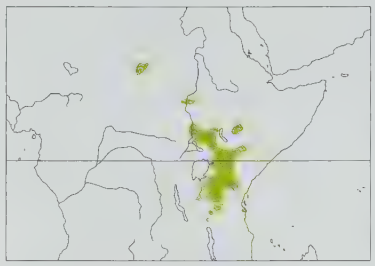
Movements. Mainly sedentary; small local movements in non-breeding season.

Status and Conservation. Not globally threatened. Common. Largely dependent on cultivated crops; not directly controlled by man, but breeding area may be abandoned after a few years, the birds moving to a new location. Could possibly be put at risk through removal of trees on which it depends for cover and breeding. Presence in Africa is result of recent expansion of range, possibly resulting from escaped cagebirds; is still spreading W, the gap between it and *P. luteus* having decreased from 650 km in 1970 to less than 50 km in 2000.

Bibliography. Al-Safadi & Kasparek (1995), Archer & Godman (1961), Ash (1980), Ash & Atkins (2009), Ash & Miskell (1983, 1998), Bowden (1987), Clement *et al.* (1993), Fry & Keith (2004), Meinertzhagen (1954), Neunzig (1928), Porter *et al.* (1996), Redman *et al.* (2009), Ruelle (1992a).

26. Chestnut Sparrow

Passer eminibey



French: Moineau d'Emin **German**: Maronensperling **Spanish**: Gorrión Castaño
Other common names: Emin Bey's Sparrow

Taxonomy. *Sorella eminibey* Hartlaub, 1880, Lado, northern Uganda.

Formerly placed in a monotypic genus, *Sorella*. Has been placed in the superspecies formed by *P. luteus* and *P. euchlorus*, but this arrangement considered doubtfully valid. Monotypic.

Distribution. W, SE & S Sudan, S Ethiopia, N & NE Uganda and much of Kenya S to NE, C & E Tanzania.

Descriptive notes. 10·5–11·5 cm; 12–17 g. Male is dark chestnut, becoming darker and browner on face; blackish-brown wing and tail with chestnut edges, small pale patch at base of primaries; iris dark brown; bill black or blackish; legs pale brown. Female has head to upper mantle grey-brown, chestnut-buff supercilium, chestnut chin and centre of throat, chestnut-brown lower mantle and scapulars streaked dark brown, back to uppertail-coverts more rufous; tail and wing similar to male's, but edges paler and buffer; chest dull chestnut, becoming buff on belly and flanks; bill paler than male's. Juvenile is similar to female but paler, with chestnut reduced to tinge on rump and lesser upperwing-coverts (chestnut almost entirely absent on throat and face); immature male becomes blotched with chestnut, and may even breed in this plumage. Voice. Song thin, high-pitched "tchiweeza tchiweeza tchi-tchi-tchi-tchi see-see-see-see-seerichi"; threat a dry scolding "chrrrrit" or "chrrreerrrrrrrr"; flight call ringing "chew chew".

Habitat. Dry acacia (*Acacia*) savanna near swamps or habitations, up to 2200 m.

Food and Feeding. Mostly granivorous, taking seeds of grasses and weeds; also household scraps. Nestlings fed with insects, including small beetles (Coleoptera), and soft grass seeds. Feeds on ground. Forages in small groups and in flocks; also singly and in pairs.

Breeding. Breeding coincides with rains and can take place at any time of year, apparently stimulated by breeding activity of weavers (Ploceidae). Colonial, with most unusual behaviour; sometimes in single-species colony, and sometimes in mixed colony with e.g. Speke's (*Ploceus spekei*) and Lesser Masked Weavers (*Ploceus intermedius*) and/or Grey-capped Social Weaver (*Pseudonigrita arnaudi*). Nest an untidy globular structure with side entrance, built from dry grass, lined with feathers, placed in branches of tree; often old abandoned nest of weaver, including aforementioned species, used; sometimes, in mixed colony with weavers, uses old nests of latter or ejects owners from occupied nest (in some colonies, ejection of owners was the sole strategy); suggested that present species is evolving from normal breeder into nest parasite. Clutch 3–4 eggs; in captivity, incubation period 18–19 days; chicks possibly fed by female alone, no information on duration of nestling period.

Movements. Nomadic, wandering extensively in large flocks outside breeding season.

Status and Conservation. Not globally threatened. Local, but common.

Genus *CARPOSPIZA* J. W. von Müller, 1854

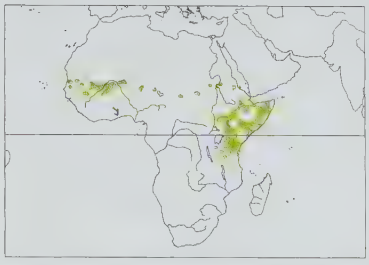
27. Pale Rock-sparrow

Carpospiza brachydactyla

French: Moineau pâle **German**: Fahlsperling **Spanish**: Gorrión Pálido
Other common names: Pale Rockfinch/Petronia, Hill Sparrow

Taxonomy. *Petronia brachydactyla* Bonaparte, 1850, "Abyssinia, Arabia" = Kunfuda, western Arabia.
Genus often subsumed into *Petronia*. This species, however, differs strikingly from other rock-sparrows, and considered by some authorities to be a cardueline finch (Fringillidae); similar to latter in breeding details (nest, eggs, appearance of nestling), in having only partial juvenile moult and in song, but differs in details of cranium; affinity to sparrows supported by structure of horny palate and digestive tract. Further study required. Monotypic.
Distribution. Breeds SE Turkey, N Middle East, erratically in Saudi Arabia and United Arab Emirates, and Armenia E to Iran, Turkmenistan and W Afghanistan.

Descriptive notes. 13·5–14·5 cm; 21–25 g. Slim, generally rather featureless sparrow with short and stout bill; in flight, long triangular-shaped wings reminiscent of a lark (Alaudidae). Has top of head light sandy grey, poorly defined pale supercilium and area under eye; side of head pale greyish-brown, paler moustachial stripe, contrasting darker malar streak; upperparts light sandy grey, slightly darker on uppertail-coverts; upperwing mostly dark brown, median and greater coverts with broad buff tips (double buff wingbar), flight-feathers with pale sandy edges and tips (pale panel on secondaries); tail rather dark grey-brown, feathers narrowly edged paler, tips of all except central pair white; chin and throat whitish to pale buff, breast and upper flanks darker, buffish-grey, rest of underparts white with variable light buff wash; iris dark brown; bill pale brown; legs bright orange-brown. Sexes alike. Juvenile is similar to adult, but paler. Voice. Call a high-pitched nasal "twee", "zweee" or "twee-oo"; song monotonous insect-like buzzing "tss tss tss tsseeeeeee", usually from top of rock or bush. Soft trill or churr in flight; during nest-building and incubation, partners give duetting calls near nest.
Habitat. Arid regions with sparse bushy vegetation, often in sparsely grassed hilly and mountainous areas, and rocky ravines; to 3000 m. Occurs in open cultivated land in non-breeding quarters.
Food and Feeding. Mostly plant matter, especially seeds, including those of cultivated cereals, and green parts of plants; also insects in breeding season. Nestlings fed mainly with caterpillars and small cicadas (Cicadidae). Forages on ground and among low vegetation. In pairs and in small, loose groups; larger flocks in non-breeding season.
Breeding. Thought to be an opportunistic breeder, following exceptional rains, Mar in S of range to Jul in N; single-brooded. In loose colonies. Nest an open, bulky, untidy hemisphere of thorny twigs, plant stems and grass, lined with plant down and animal hair, placed in bush or sometimes in crevice in rock or hole in building. Clutch 3–6 eggs, generally 4–5; incubation by female alone, period 13–14 days; chicks fed by both parents, nestling period 11–16 days.
Movements. Migratory. Non-breeding quarters mainly in W Saudi Arabia and NE Africa (EC & E Sudan, Eritrea, Djibouti and N Ethiopia), occasionally in S Israel, Egypt and Oman. Departure from breeding quarters mid-Jul to mid-Aug; leaves non-breeding grounds from middle of Feb, peak passage mid-Mar to mid-April in much of Arabia and sometimes large flocks recorded (e.g. 1200 in mid-Mar in United Arab Emirates); arrival in breeding areas mostly in second half May.
Status and Conservation. Not globally threatened. Locally common, and abundant in some parts of range. Flocks of several hundreds can pose a threat as a pest of cereal (millet) cultivation.
Bibliography. Adamyan (1965), Ash & Atkins (2009), Bock (2004), Clement *et al.* (1993), Cramp & Perrins (1994), Dementiev *et al.* (1954, 1970), Flint *et al.* (1984), Gallagher & Woodcock (1980), Griffin *et al.* (2001), Hüe & Étchécopar (1970), Ivanitskii (1986, 1997), Kirwan (1998), Kirwan *et al.* (2008), Knight & Beale (2004), Mackworth-Praed & Grant (1960), Patrikeev (2004), Porter *et al.* (1996), Rasmussen & Anderton (2005b), Redman *et al.* (2009), Scott *et al.* (1975), Shirihai (1996), Stepanyan (2003), Vaurie (1959), Zusi (1978).



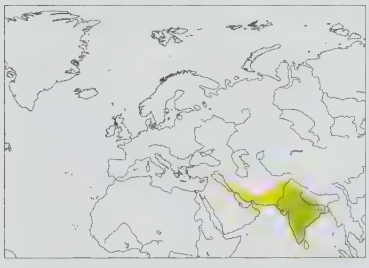
Genus *GYMNORIS* Blyth, 1845

28. Yellow-spotted Bush-sparrow

Gymnoris pyrgita

French: Moineau à point jaune **German**: Sahelsteinsperling **Spanish**: Gorrión Moteado
Other common names: Yellow-spotted Petronia/Rock-sparrow, Abyssinian Yellow-throated Petronia, Sudan Rock-sparrow/Petronia

Taxonomy. *Xanthodina pyrgita* Heuglin, 1862, Bogos Mountains, slopes of the Barca valley, Eritrea.
Genus often subsumed into *Petronia*. Forms a superspecies with *G. xanthocollis*, and sometimes treated as conspecific. Two subspecies recognized.
Subspecies and Distribution.
G. p. pallida Neumann, 1908 – S Mauritania and W Senegal E, very patchily, to C Sudan.
G. p. pyrgita (Heuglin, 1862) – Eritrea, SE Sudan, S Ethiopia and Somalia S to NE Uganda, Kenya and N Tanzania.



Descriptive notes. 15–16 cm; 21–28·5 g. Nominate race is unstreaked ash-grey to ashy brown above, with indistinct narrow light buff supercilium, white ring around eye, cheek dusky brown; tail dark brown with greyish-buff edges to outer feathers; chin and throat whitish, yellow spot on lower throat (often difficult to see in field); breast greyish, rest of underparts plain dirty white, belly paler; iris dark brown; bill pinkish-horn; legs blue or bluish-grey. Sexes similar, throat spot of female sometimes less distinct than male's. Juvenile is similar to adult, but somewhat browner, with more conspicuous supercilium, and some streaking on back. Race *pallida* is paler and sandier above and clearer white below than nominate. Voice. Calls include shrill "tyit", "tyeet" and "chillip", and lower-pitched, chirping "tlooey-tlooey" or "cherp-cherp"; song a simple "chiew-chiew-chiew-chiew-tcheep".
Habitat. Dry savanna, acacia (*Acacia*) steppe and open woodland, gardens and cultivated land with trees; to 1800 m. Some preference for rocky ground, but seen more often in trees than on ground.
Food and Feeding. Berries of toothbrush tree (*Salvadora persica*), seeds; also insects, including beetles (Coleoptera). Forages on ground, but probably equally or more in trees; searches for insects in trees in manner of a tit (Paridae). Forages in pairs and small groups; often in company of small weavers (Ploceidae).
Breeding. Mainly Jun–Aug in W of range, May in Somalia and Mar–Apr in Kenya and Tanzania, coinciding with rains. Solitary. Nest a pad of hair, feathers and other soft material, placed in hole in tree branch, stump or sand cliff. Clutch 3–5 eggs. No other information.
Movements. Nomadic outside breeding season.
Status and Conservation. Not globally threatened. Common; apparently very local in much of range.
Bibliography. Ash & Atkins (2009), Borrow & Demey (2001), Britton (1980), Brown & Britton (1980), Clement *et al.* (1993), Dickinson (2003), Friedmann (1937), Fry & Keith (2004), Grant & Mackworth-Praed (1944a), Hall & Moreau (1970), Mackworth-Praed & Grant (1960), Nikolaus (1987), Redman *et al.* (2009), Williams & Arlott (1980).

29. Chestnut-shouldered Bush-sparrow

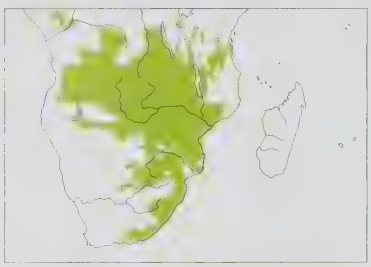
Gymnoris xanthocollis

French: Moineau à gorge jaune **German**: Gelbkehlsperling **Spanish**: Gorrión Cuelligualdo
Other common names: Chestnut-shouldered Petronia/Sparrow, Yellow-throated Sparrow/Rock-sparrow/Petronia

Taxonomy. *Fringilla xanthocollis* E. Burton, 1838, Ganges between Calcutta and Benares, India.
Genus often subsumed into *Petronia*. Forms a superspecies with *G. pyrgita*, and sometimes treated as conspecific. Two subspecies recognized.
Subspecies and Distribution.
G. x. transfuga E. J. O. Hartert, 1904 – SE Turkey, SE Iraq, SW Afghanistan and S Pakistan; possibly also the Syrian Euphrates.
G. x. xanthocollis (E. Burton, 1838) – E Afghanistan and N Pakistan E to S Nepal, and most of India.

Descriptive notes. 12·5–14 cm; 14–20 g. Smallish drab sparrow with comparatively long and slender bill. Male nominate race is mainly olive grey-brown above and pale brown to whitish below, unstreaked; can have faint pale supercilium (often more marked in female); small, rather inconspicuous pale yellow spot on lower throat; chestnut patch on forewing, two prominent white wingbars; tail slightly notched at tip, dark grey with thin paler buffy edges; iris dark brown; bill horn-coloured, becoming black in breeding season; legs grey or grey-brown. Female is like male but duller, lacks yellow throat spot and chestnut forewing; bill yellowish-horn, paler at base. Juvenile resembles female. Race *transfuga* is paler, more sandy, than nominate. Voice. Chirping calls, similar to "chilp" or chirrup" of *Passer domesticus* but softer and more tuneful; song, given for long periods from favoured perch, a rhythmic "chilp chalp cholp", more melodious and faster than that of *P. domesticus*.
Habitat. Open country and low hills with trees, river bottoms with trees, and scrub-jungle, also cultivated areas with scattered trees or hedgerows, villages and inhabited areas with gardens. To 1500 m.
Food and Feeding. Plant material, mainly seeds, including those of cultivated cereals, also small berries and nectar (forehead often discoloured golden by pollen); in breeding season also insects, mainly weevils (Curculionidae), caterpillars, grasshoppers (Orthoptera) and ants (Formicidae). Nestlings fed with insects. Forages in trees, but mostly on ground. Gregarious; in pairs and small groups, with larger flocks outside breeding season.
Breeding. Apr–Jul in Afghanistan and mainly Feb–May in India; two broods. Solitary or in small groups. Nest built by female, ranges from being a small pad of hair, feathers and grass to being an untidy mass of dry grass, wool and hair, lined with feathers, that fills cavity in which placed, mainly in covered site, including crevice in tree or hole in wall or building, also in old nest of other species. Clutch 3–4 eggs, occasionally 5; incubation by female alone, chicks fed by both sexes; no information on duration of incubation and nestling periods.
Movements. In NW & N of range, from Turkey E to Pakistan and N India, a summer visitor; in S a partial migrant, some moving to S of breeding range in winter. Also nomadic, making local movements apparently in response to rain. Vagrant in Malta, Israel and Sri Lanka.

On following pages: 30. Yellow-throated Bush-sparrow (*Gymnoris superciliaris*); 31. Russet-browed Bush-sparrow (*Gymnoris dentata*); 32. Common Rock-sparrow (*Petronia petronia*); 33. White-winged Snowfinch (*Montifringilla nivalis*); 34. Black-winged Snowfinch (*Montifringilla adamsi*); 35. Tibetan Snowfinch (*Montifringilla henrici*); 36. White-rumped Ground-sparrow (*Pyrgilauda taczanowskii*); 37. Small Ground-sparrow (*Pyrgilauda davidiana*); 38. Rufous-necked Ground-sparrow (*Pyrgilauda ruficollis*); 39. Blanford's Ground-sparrow (*Pyrgilauda blanfordi*); 40. Afghan Ground-sparrow (*Pyrgilauda theresae*).



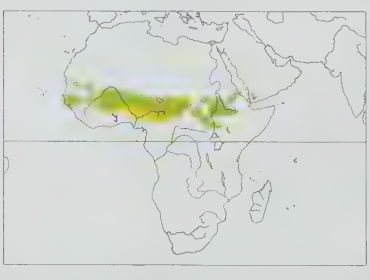
Status and Conservation. Not globally threatened. Common; locally abundant in Indian Subcontinent.
Bibliography. Ali & Ripley (1974), Clement *et al.* (1993), Cramp & Perrins (1994), Dickinson (2003), Fleming *et al.* (1979), Gallagher & Woodcock (1980), Hüe & Etchécopar (1970), Kirwan *et al.* (2008), Murdoch (2005), Porter *et al.* (1996), Rasmussen & Anderton (2005b), Roberts (1992), Scott *et al.* (1975), Vaurie (1959).

30. Yellow-throated Bush-sparrow

Gymnoris superciliaris

French: Moineau bridé **German**: Kapsteinsperling **Spanish**: Gorrión Cejudo
Other common names: Yellow-throated Petronia, (Southern) Yellow-throated Sparrow, South African Petronia/Rock-sparrow

Taxonomy. *Gymnorhis* [sic] *superciliaris* Blyth, 1845, Cape Town, South Africa.
Genus often subsumed into *Petronia*. Geographical variation rather poorly marked; species sometimes treated as monotypic. Proposed race *oraria* (described from Magogoni, inland from Dar es Salaam, in E Tanzania) is synonymous with *hororensis*. Four subspecies recognized.
Subspecies and Distribution.
G. s. rufitergum (Clancey, 1964) – extreme SE Gabon, S PRCongo and SW & S DRCongo E to SW Tanzania, S to Angola, NE Namibia and NW Botswana.
G. s. flavigula (Sundevall, 1850) – SE Zambia, Zimbabwe, E Botswana and N South Africa.
G. s. hororensis (Roberts, 1912) – E Tanzania S to Mozambique, NE South Africa (E Limpopo Province and NE KwaZulu-Natal) and E Swaziland.
G. s. superciliaris Blyth, 1845 – E South Africa (KwaZulu-Natal S to Eastern Cape).



Descriptive notes. 15–16 cm; 22–30 g. Nominate race is dusky brown above, with prominent broad whitish-buff supercilium from just in front of eye broadening out towards nape, bordered below by blackish-brown eyestripe behind eye and curving down behind ear-coverts; back streaked dusky, upperwing-coverts tipped pale buffish; tail dark brown with narrow pale or warm buffish-brown edges; chin whitish, throat white, inconspicuous yellow spot on lower throat; underparts brownish-grey, becoming off-white in centre of belly; iris dark brown; bill robust, brown with paler lower mandible; legs dark grey. Sexes alike. Juvenile is like adult, but generally warmer brown, with supercilium buffish, and lacks yellow throat spot. Races differ mainly in colour of upperparts: *hororensis* is more buffy above; *flavigula* is somewhat paler; *rufitergum* is tinged rufous. Voice. Calls include disyllabic "chlee-chlee" or "chew-chew", and single "pick" or "peek"; song a series of tuneless chirping notes (up to 7 in a series), "tyee-tyee-tyee" or "tyoo-tyoo-tyoo-tyoo", or faster "chichichichichichichew". Low chatter/scold presumably used in threat.
Habitat. Widespread in woodland, savanna, riverine bush and cultivated land, especially in hilly districts; to 1500 m, occasionally higher.
Food and Feeding. Seeds, nectar and insects. Forages on ground, but more usually in higher branches of trees. Singly, in pairs and in small groups; small flocks outside breeding season.
Breeding. Season Aug–Nov in DRCongo, Zambia, Zimbabwe and N South Africa (Limpopo), Oct–Nov in Mozambique, Oct–Jan in E South Africa and Jan–Feb in Namibia, coinciding with rains. Solitary. Nest a loose ball of grass with thick lining of feathers, placed in shallow hole in tree. Clutch 3–4 eggs; incubation by female alone, period 17 days; chicks fed by both parents, nestling period 18–19 days.
Movements. Resident; some local wandering outside breeding season.
Status and Conservation. Not globally threatened. Common to locally uncommon. Density up to 16 birds/ha. Estimated population in Swaziland 4000 individuals and in S Mozambique 50,000 individuals.
Bibliography. Benson & Benson (1977), Benson *et al.* (1973), Borrow & Demey (2001), Britton (1980), Brown & Britton (1980), Chapin (1954), Clancey (1971a), Clement *et al.* (1993), Dickinson (2003), Dowsett *et al.* (2008), Fry & Keith (2004), Harrison *et al.* (1997), Hockey *et al.* (2005), Mackworth-Praed & Grant (1963), Maclean (1985).

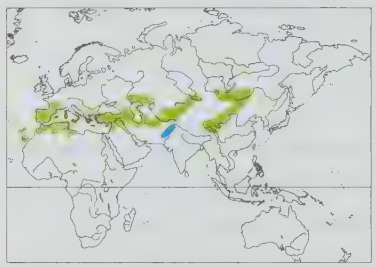
31. Russet-browed Bush-sparrow

Gymnoris dentata

French: Petit Moineau **German**: Buschsteinsperling **Spanish**: Gorrión Chico
Other common names: Bush Petronia/Sparrow, Lesser Petronia/Rock-sparrow

Taxonomy. *Xanthodira dentata* Sundevall, 1850, Ronga [=Abu Saad], on Blue Nile, Sudan.
Genus often subsumed into *Petronia*. Race *buchanani* rather weakly differentiated; species sometimes treated as monotypic. Two subspecies recognized.
Subspecies and Distribution.
G. d. dentata (Sundevall, 1850) – S Mauritania and Senegambia E in Sahel zone and savanna belt (except S Niger) to S Sudan, W Ethiopia and N Eritrea; also SW Arabia (S Yemen).
G. d. buchanani E. J. O. Hartert, 1921 – S Niger (Zinder province E to L Chad).

Descriptive notes. 13 cm; 16–21·5 g. Fairly small sparrow with relatively short tail and long conical bill. Male nominate race is mainly dark brown above, with grey crown separated from grey ear-coverts and cheek by russet supercilium extending from eye to side of nape and down side of neck; rather indistinct pale tip on upperwing-coverts; tail dark grey or greyish-brown, with narrow pale edges and buffish to buffy-white tips; chin and throat creamy white, inconspicuous small pale yellow spot on lower throat; underparts off-white, breast and flanks washed grey; iris dark brown; bill brown with paler-horn base, becoming black in breeding season; legs grey, bluish-grey or brown-tinged greyish. Female is similar to male, but with crown browner, supercilium cream, dark streaks on back, yellow throat spot reduced or lacking. Juvenile is like female, but upperparts more tawny-brown and supercilium tawny-buff. Race *buchanani* is paler than nominate. Voice. Calls chirping; song slightly rolled "chru-chru-chru-chru-chru-chru-chru", similar to that of *G. superciliaris* but lower-pitched and drier.
Habitat. Dry and arid areas, wooded savanna to light woodland, and cultivated clearings in vicinity of towns, to 1500 m; to 1900 m in Yemen.
Food and Feeding. Small seeds and insects. Obtains food items both from the ground and by searching branches and leaves on trees. Spends most of time in trees. Singly, in pairs and in small groups; sometimes larger concentrations at food sources.
Breeding. Season Nov–Mar over most of range. Solitary. Nest cup-shaped, placed in hole in tree or post or crevice in tree, occasionally a shapeless mass of grass in tree branches; often in old hole of woodpecker (Picidae) in Yemen. No other information on wild populations; in captivity, clutch 2–3 eggs, incubation by both sexes, mainly female, period 14–17 days, chicks fed by both parents, nestling period 13 days.
Movements. Resident and local migrant, wandering widely outside breeding season.
Status and Conservation. Not globally threatened. Uncommon to locally fairly common in W of range; frequent to common in E, and locally abundant in Eritrea.
Bibliography. Ash & Atkins (2009), Borrow & Demey (2001), Clement *et al.* (1993), Dickinson (2003), Fry & Keith (2004), Hall & Moreau (1970), Mackworth-Praed & Grant (1973), Nikolaus (1987), Porter *et al.* (1996), Redman *et al.* (2009), Trollope (1977).



Genus *PETRONIA* Kaup, 1829

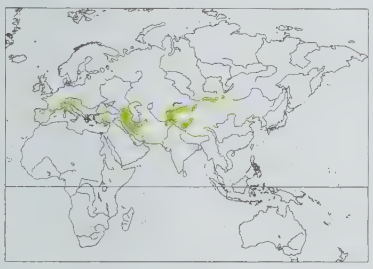
32. Common Rock-sparrow

Petronia petronia

French: Moineau soulcie **German**: Steinsperling **Spanish**: Gorrión Chillón
Other common names: Rock Sparrow/Petronia, Eurasian/European/Streaked Rock-sparrow

Taxonomy. *Fringilla Petronia* Linnaeus, 1766, northern Italy.
Somewhat smaller birds from Caspian region E to Kyrgyzstan sometimes treated as additional race *kirhizica*, but differences from *intermedia* appear insufficient to justify separation. Six subspecies recognized.
Subspecies and Distribution.
P. p. petronia (Linnaeus, 1766) – Madeira, Canary Is, and S Europe (including Mediterranean islands) E to Bulgaria and W Asia Minor.
P. p. barbara Erlanger, 1899 – Morocco E to NW Libya (S to 21° N).
P. p. exigua (Hellmayr, 1902) – C Turkey E to Caucasus, N Iraq and N Iran (E to Gorgan).
P. p. puteicola Festa, 1894 – S Turkey S to C Israel, Syria and W Jordan.
P. p. intermedia E. J. O. Hartert, 1901 – lower Volga valley E to Aral Sea and E Kazakhstan, Kyrgyzstan, S to SW & NE Iran, N Afghanistan and extreme NW China (W Xinjiang).
P. p. brevirostris Taczanowski, 1874 – S foothills of Altai, N & E Mongolia and SE Transbaikalia S to N & C China (Inner Mongolia S to N Sichuan).

Descriptive notes. 14–15·5 cm; 26–39 g. Stout sparrow with short, square tail and robust bill; in flight, broad wings and short, white-tipped tail characteristic. Nominate race is mainly greyish-brown, heavily streaked darker brown above and below; head boldly striped, with pale crown, dark brown lateral crownstripe, and conspicuous buffy-white stripe extending back from eye and bordered below by dark line behind eye; upperparts brown with darker brown streaking; tail with white spots on tip; whitish below, inconspicuous yellow spot on lower throat (not easy to see in field), underparts streaked grey-brown; iris dark brown; bill horn to dark brown above, almost entirely horn-yellow below; legs pale brown or pinkish-brown. Sexes alike. Juvenile is browner than adult, duller below, lacks yellow throat spot. Race *barbara* is paler and greyer than nominate; *exigua* is intermediate between nominate and previous; *puteicola* is larger than nominate, palest race, streaking on underparts much less obvious; *intermedia* is intermediate between nominate and last; *brevirostris* has shorter and heavier bill. Voice. Noisy. Large variety of mainly disyllabic, rather nasal calls, e.g. "pee-yee" or "jee-wee"; song a loose collection of up to 50 varied call notes. Threat a chattering "terrettettet", similar to that of *Passer domesticus*.
Habitat. Generally bare treeless country, ranging from flat desert steppe to rocky slopes and ravines at up to 4800 m; in Spain, common in open woodland or parkland, e.g. of maritime pine (*Pinus pinaster*). Frequently forages in large open areas of cultivation, vineyards, olive groves, near old buildings and even penetrates into human settlements.
Food and Feeding. Mainly seeds of low herbs and grasses, also small berries; in breeding season also animal matter, e.g. termites (Isoptera) and beetles (Coleoptera), taking larger prey than do members of *Passer*. Nestlings fed mainly with invertebrates, especially caterpillars of Lepidoptera and grasshoppers (Orthoptera). Food collected mostly on the ground, but some insects caught in flight. In pairs and in small flocks, often in larger flocks.
Breeding. Season Mar–Aug; two broods. In loose colonies and isolated pairs. Nest an untidy structure, sometimes domed, made from grass, lined with feathers, animal hair and wool, placed in crack or crevice in rock or tree, or in wall or roof of isolated and ruined building, occasionally in occupied building, material filling cavity in which nest built. Clutch 4–7 eggs, occasionally 8; incubation by female only, period 11–14 days; chicks fed by female, male sometimes taking minor role, nestling period 18–19 days.
Movements. Resident and partial migrant; some post-breeding dispersal and withdrawal to lower altitudes in winter. Race *intermedia* found in winter also in S Afghanistan, Kashmir and N Pakistan.
Status and Conservation. Not globally threatened. Common. European population in 1980s estimated at c. 1,000,000 pairs, mostly in Spain, where breeding densities of 1·6 birds/10 ha in uncultivated land but merely 0·02 birds/10 ha in cropland; highest densities (up to 1·73 birds/10 ha) in open woodland/parkland. Recent contraction from N parts of range, although Spanish population thought to be stable during late 1990s; decrease in numbers in Madeira and Canary Is, the latter presumed to be result of competition from introduced *Passer hispaniolensis*; probably increasing in Balkans.



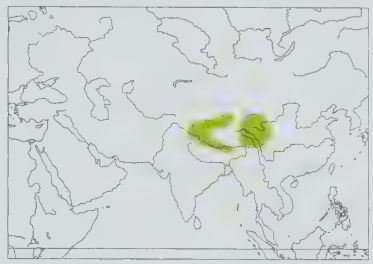
Bibliography. Biddau *et al.* (1995), Cheng Tsohsin (1987), Clement *et al.* (1993), Cramp & Perrins (1994), Dickinson (2003), Dittberner & Kage (1991), Fiebig & Jander (1987), Fry & Keith (2004), Fu Tongsheng *et al.* (1998), Griggio, Matessi & Pilastro (2003), Griggio, Tavecchia *et al.* (2003), Haffer (1997b), Hagemeijer & Blair (1997), Ivanitskii (1985, 1986), Kirwan *et al.* (2008), Martí & del Moral (2003), Matessi *et al.* (2007), Nankinov (1985), Niethammer (1967), Patrikeev (2004), Piechocki & Bołod (1972), Purroy (1997), Rasmussen & Anderton (2005b), Roberts (1992), Schäfer (1938), Scott *et al.* (1975), Stepanyan (2003), Thévenot *et al.* (2003), Vaurie (1959, 1972).

Genus *MONTIFRINGILLA* C. L. Brehm, 1828

33. White-winged Snowfinch
Montifringilla nivalis

French: Niverolle alpine **German**: Schneesperling **Spanish**: Gorrión Alpino
Other common names: Eurasian/Common Snowfinch

Taxonomy. *Fringilla nivalis* Linnaeus, 1766, Switzerland.
Forms a superspecies with *M. adamsi* and *M. henrici*, and all have in the past sometimes been considered conspecific. Races are geographically isolated from one another, and it is suggested that, in absence of gene flow, several are well towards achieving full species rank. Seven subspecies currently recognized.
Subspecies and Distribution.
M. n. nivalis (Linnaeus, 1766) – S Europe from N Spain, Pyrenees, the Alps and Corsica E to Greece.
M. n. leucura Bonaparte, 1855 – S & E Asia Minor.
M. n. alpicola (Pallas, 1811) – Caucasus, and N Iran E to Afghanistan.
M. n. gaddi Zarudny & Loudon, 1904 – Zagros Mts, in SW Iran.
M. n. tianshanica Keve-Kleiner, 1943 – W & C Tien Shan (Kazakhstan) S to N Pamirs (N Tajikistan).
M. n. groumgrzimaili Zarudny & Loudon, 1904 – E Tien Shan, NW China (N Xinjiang) and Altai to C Mongolia.
M. n. kwenlunensis Bianchi, 1908 – mountains of S Xinjiang (Kunlun, Altun Shan and Nan Shan), in SW China.

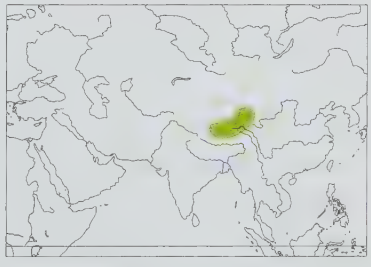


Descriptive notes. 17–17·5 cm; 31–57 g. A large, plumpish, finch-like bird with relatively long wings and tail; bill stout and pointed, longer in summer (with change in diet from harder seeds to softer insects). Male nominate race breeding has head to nape bluish-grey, black lores, black chin and throat separated from cheek by short pale stripe that joins bill; upperparts rich chocolate-brown with paler brown feather edges and tips, rump and uppertail-coverts blackish; upperwing-coverts white, alula black, primaries black with thin pale tips, secondaries white (wing showing much white, particularly in flight); tail mostly white, central feather pair and tips of all rectrices black; underparts white, breast washed light brownish-grey; iris brown; bill and legs black. Non-breeding male is similar to breeding male, but duller above, head brownish-tinged (less grey), chin and throat white with small dark feather tips, bill yellowish-horn with dark tip. Female is similar to male, but somewhat duller, with smaller, less well-defined bib; in non-breeding plumage very like non-breeding male. Juvenile is similar to female, but duller and greyer, with less white in wing and tail, bright orange-yellow bill. Races differ mainly in size and in plumage tones, to some extent also in bill length (but this requires more study, because of seasonal difference): *leucora* is larger than nominate, head and neck greyish-brown; *alpicola* is also larger and paler than nominate, grey of head somewhat bleached and brownish, back greyer brow; *gaddi* is larger and generally darker; *tianshanica* has upperparts paler, black on wing more extensive; *groumgrzimaili* also has upperparts paler, more sandy-coloured, black on wings more extensive; *kwenlunensis* is smaller and more sandy-coloured. Voice. Song, by male from high perch or in display-flight, a complex mix of varied buzzy chirps, with much repetition of individual elements such as "sitticher sitticher". Flock in flight utters harsh, nasal "pschieu" or "pchie" together with "tsee" and softer "pruuk" or "kiek"; alarm call "pititit prrt".
Habitat. Barren rocky ground with cliffs, also meadows above tree-line and up to snow-line, frequently near buildings where these present at high altitudes; 2000–5300 m.
Food and Feeding. In winter mainly seeds, including undigested seeds in droppings of horses, but also takes scraps at ski resorts; at other times of year insects, particularly grasshoppers (Orthoptera), flies (Diptera) and beetles (Coleoptera), and spiders (Araneae). Study in Switzerland in winter suggested that seeds of alpine plants are preferred over those of grasses (Gramineae). Nestlings fed almost exclusively with animal food. Food items collected mostly on ground, but some insects caught in flight. Forages in pairs and small groups; in larger flocks outside breeding season.
Breeding. Season May–Jul/Aug; two broods. Usually breeds in small loose colonies of 2–6 pairs, also solitarily; defends small territory. Pronounced circling display-flight with slowly fluttering wings. Bulky nest of dry grass and moss, lined with feathers and fine plant material, placed in crevice in rock face or hole in building, occasionally in burrow of small rodent; sometimes in artificial structure, e.g. cable-car pylon (in French Pyrenees). Clutch 4–5 eggs; incubation by female, period 12–14 days; chicks fed by both parents, nestling period 18–22 days; fledglings fed by both sexes for c. 12–15 days after leaving nest.
Movements. Mainly resident; some descent to lower altitudes in winter, particularly in E of range, but many remain near snow-line above tree-level. Vagrants recorded on Heligoland (in the German Bight), and in Canary Is, Malta, Sicily, Egypt and Iraq.
Status and Conservation. Not globally threatened. Common, but generally local. Has probably benefited from increased winter occupation of alpine resorts by humans. European population in 1980s was estimated at 15,000–23,000 birds. Breeding densities range from 20 birds/km² in Cantabrian Mts (Spain) and 9·4–11·7 pairs/km² in French Pyrenees to 4·5–11·5 birds/km² in the Alps.
Bibliography. Busching (2003), Cheng Tsohsin (1987), Clement *et al.* (1993), Cramp & Perrins (1994), Dickinson (2003), Étchécopar & Hüe (1983), Flint *et al.* (1984), Fu Tongsheng *et al.* (1998), Gebauer & Kaiser (1994), Gebauer *et al.* (2006), Grangé (2008), Haffer (1997c), Hagemeijer & Blair (1997), Kirwan *et al.* (2008), Malle (2006), Patrikeev (2004), Piechocki & Bołod (1972), Portenko & Vietinghoff-Scheel (1974a), Qu Yanhua, Ericson *et al.* (2006), Qu Yanhua, Lei Fumin *et al.* (2002), Rasmussen & Anderton (2005b), Roberts (1992), Stegmann (1932), Vaurie (1959), Wehrle (1989), Ziswiler (1967).

34. Black-winged Snowfinch
Montifringilla adamsi

French: Niverolle du Tibet **German**: Adamsschneesperling **Spanish**: Gorrión de Adams
Other common names: Adams's Snowfinch

Taxonomy. *Montifringilla Adamsi* Adams, 1859, Ladakh, India.
Forms a superspecies with *M. nivalis* and *M. henrici*, and all have in the past sometimes been considered conspecific. Two subspecies recognized.
Subspecies and Distribution.
M. a. adamsi Adams, 1859 – N Kashmir and Ladakh NE along N Tibetan Plateau to Kunlun Shan (in Xinjiang), and SE along Himalayan chain to Sikkim (N India).
M. a. xerophila Stegmann, 1932 – C China from NE Qinghai (Qilian Shan) S to E Tibetan Plateau and SC Sichuan (Litang).



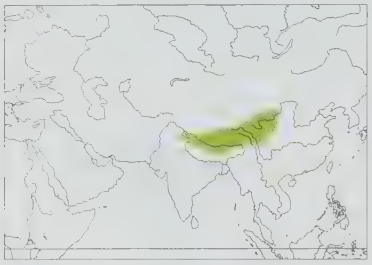
Descriptive notes. 17 cm. Nominate race has head grey-brown, faint paler supercilium and submoustachial streak, black chin and throat with small whitish feather tips; upperparts grey-brown with dark streaks, rump and uppertail-coverts blackish-brown; median upperwing-coverts dark brown with broad white fringes, greater coverts white (sometimes some brown on inner webs of some), alula dark brown, primary coverts white with dark tips, primaries blackish-brown with narrow pale edges, secondaries blackish with whitish distal half; tail white, central feather pair black, all rectrices with black tip; underparts creamy white, breast washed buff; iris brown; bill horn-coloured, becoming black in breeding season; legs black. Differs from similar *M. nivalis* mainly in having less contrasting plumage, less white in wing. Female has throat spot fainter, black of wings slightly browner. Juvenile is similar to adult, but warmer brown, with less white in wing, throat greyish, yellow bill base. Race *zerophila* is paler than nominate. Voice. Song a distinctive single note repeated rather monotonously from top of rock or during display-flight. Call a sharp, strident "pink pink". Large flocks keep up a constant soft twittering.
Habitat. Occupies rocky, high-altitude steppe country and the neighbourhood of upland villages; near edges of streams and melting snowfields. At 3500–5200 m, but usually at lower altitudes than *M. nivalis*.
Food and Feeding. Seeds of alpine plants and insects. Forages on ground, searching under rocks, commonly at edge of snowfields, and catches insects in flight. In pairs and family groups; outside breeding season in flocks, sometimes very large ones.
Breeding. Season May–Jul. Breeds in loose colonies or isolated pairs. Has well-developed parachuting display-flight, hovering and falling with wings and tail outspread. Nest a cup of grass, wool and similar material, lined with hair, feathers and fragments of wool, normally placed in rock crevice or hole under boulder, less commonly in burrow of pika (*Ochotona*). Clutch 4 eggs; incubation probably by both sexes; chicks fed by both adults. No other information.
Movements. Nomadic, forming large flocks after breeding; tendency to remain at high altitudes through the winter months.
Status and Conservation. Not globally threatened. Fairly common to common; rare and irregular in Sikkim.
Bibliography. Ali & Ripley (1974), Cheng Tsohsin (1987), Clement *et al.* (1993), Dickinson (2003), Étchécopar & Hüe (1983), Fu Tongsheng *et al.* (1998), Gebauer & Kaiser (1994), Gebauer *et al.* (2006), Li Dehao *et al.* (1978), Portenko & Vietinghoff-Scheel (1974b), Qu Yanhua, Ericson *et al.* (2006), Qu Yanhua, Lei Fumin *et al.* (2002), Rasmussen & Anderton (2005b), Roberts (1992), Schäfer (1938), Stegmann (1932), Vaurie (1959, 1972).

35. Tibetan Snowfinch
Montifringilla henrici

French: Niverolle de Henri **German**: Tibetschneesperling **Spanish**: Gorrión de Henri

Taxonomy. *Eurhinospiza Henrici* Oustalet, 1892, "plateau du Tibet" = Dichi (Diti) east of the Tengri Nor, Xizang, China.
Forms a superspecies with *M. nivalis* and *M. adamsi*, and all have in the past sometimes been considered conspecific. Often treated as a race of *M. nivalis*, and sometimes of *M. adamsi*, but overlaps with latter without interbreeding in parts of its range. Monotypic.
Distribution. E Tibetan Plateau from Qinghai Hu (NE Qinghai) S in band 100–250 km broad to Ku-la Shan, NE of Lhasa (Xizang).

Descriptive notes. 17 cm; 40 g. Male has head and nape earth-brown; mantle, back and scapulars dark brown, large white patch on wing (noticeable in flight); small black bib; underparts grey, flanks washed rusty brown; iris brown; bill horn-coloured, becoming black during breeding; legs black. Differs from very similar *M. nivalis* mainly in larger size and generally darker and duller plumage. Female is slightly duller than male, with bib smaller. Juvenile apparently undescribed. Voice. No detailed information. Generally similar to that of *M. nivalis*.
Habitat. High-altitude steppe country from above trees to snow-line; 2500–4500 m.
Food and Feeding. Seeds and plant matter; young reared on insects, both larval and adult forms of beetles (Coleoptera) and flies (Diptera), and arachnids. In small groups and larger flocks.
Breeding. Pairs take up nesting territories in Apr/May, breeding Jun–Aug. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. Few data available. Reckoned to be fairly common.
Bibliography. Cheng Tsohsin (1987), Clement *et al.* (1993), Fu Tongsheng *et al.* (1998), Gebauer & Kaiser (1994), Gebauer, Eck *et al.* (2006), Gebauer, Kaiser & Eck (2003), Martens & Eck (1995), Moreau & Greenway (1962), Schäfer (1938), Stegmann (1932), Vaurie (1956, 1959).



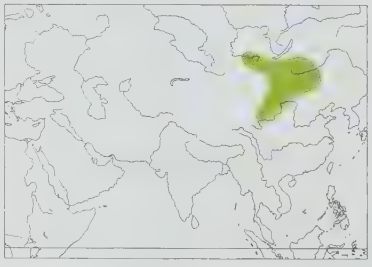
Genus *PYRGILAUDA* J. Verreaux, 1870

36. White-rumped Ground-sparrow

Pyrgilauda taczanowskii

French: Niverolle de Taczanowski **Spanish**: Gorrión de Taczanowski
German: Weißbürzel-Erdsperling
Other common names: White-rumped Snowfinch, Taczanowski's/Mandelli's Ground-sparrow/Snowfinch

Taxonomy. *Montifringilla taczanowskii* Przevalski, 1876, Tetunga and Koko Nor Steppe, west China.
Genus often subsumed into *Montifringilla*. On basis of recent studies, some authorities consider this species sufficiently differentiated in behaviour and molecular genetics from the other ground-sparrows to warrant placement in a separate genus, *Onychostruthus*; differences are, however, marginal, and it is retained in present genus pending further study. Monotypic.
Distribution. SE Ladakh and S & E Tibetan Plateau E to NE Qinghai (Qilian Mts and area around Qinghai Hu), SW Gansu and NW Sichuan, in C China, and S to N Nepal and Sikkim.



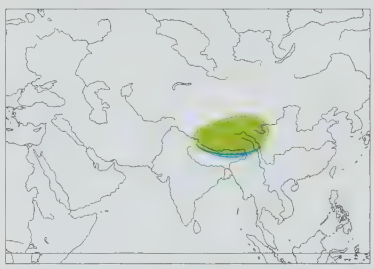
Descriptive notes. 15–17cm; 29–36 g. Large ground-sparrow with stout and rather pointed bill and long legs. Crown and nape are grey-brown, paler on forehead and supercilium, lores black; upperparts grey-brown, dark brown streaking on mantle and upper back, plain white rump; tail dark brown, outer feathers increasingly white towards tip; median upperwing-coverts blackish, tipped white, greater coverts dark brown with pale buffy edges (inner greater coverts with more white), alula and primary coverts blackish, flight-feathers blackish, broad white panel at base, primaries edged white, secondaries edged pale buff; chin and throat white, underparts ashy white, breast and flanks washed greyish-buff; iris brown; bill pale horn with dark tip; legs black. Sexes alike. Juvenile is similar to adult, but warmer brown in colour. Voice. Call a sharp and resounding "duid duid". Song based on this call, a short, loud "duid-ai-duid duid duid ai", given in display-flight similar to that of larks (Alaudidae).
Habitat. Barren alpine rocky areas and flat steppe on dry edges of bogs; associated with colonies of pika (*Ochotona*), using burrows for both roosting and breeding. Moves into neighbourhood of human habitations in winter. At 3500–5100 m.
Food and Feeding. Small seeds and insects. Forages on ground, turning over small stones and digging into soil; in non-breeding season, searches for insects in dung of domestic animals near human habitations. Runs rapidly on its long legs. Singly and in pairs; in larger flocks in non-breeding season.
Breeding. Two nests with young in Jul. Breeds in solitary pairs or in small groups. Strongly territorial; has undulating display-flight, also steep climb and diving descent. Nest a mat of roots and grasses, lined with fur and feathers, placed well inside hole of small mammal, particularly black-lipped pika (*Ochotona curzoniae*), scraping out soil with its strong feet. Clutch 3–5 eggs. No other information.
Movements. Mainly sedentary; some seasonal short-distance movements to lower altitudes in winter.
Status and Conservation. Not globally threatened. Common in much of range; scarce in S, e.g. Ladakh and Nepal.
Bibliography. Ali & Ripley (1974), Cheng Tsohsin (1987), Clement *et al.* (1993), Dickinson (2003), Eck (1996), Étchécopar & Hüe (1983), Fu Tongsheng *et al.* (1998), Gebauer & Kaiser (1994), Gebauer *et al.* (2006), Lei Fumin *et al.* (2004), Neufeldt & Vietinghoff-Scheel (1978a), Qu Yanhua & Lei Fumin (2009), Qu Yanhua, Ericson *et al.* (2006), Qu Yanhua, Lei Fumin & Yin Zuohua (2004), Qu Yanhua, Lei Fumin, Yin Zuohua & de Ritis (2002), Rasmussen & Anderton (2005b), Schäfer (1938), Vaurie (1959, 1972), Yang *et al.* (2006).

37. Small Ground-sparrow

Pyrgilauda davidiana

French: Niverolle de David **German**: Daviderdsperling **Spanish**: Gorrión de David
Other common names: (Père) David's Ground-sparrow/Snowfinch, Mongolian/Small Snowfinch

Taxonomy. *Pyrgilauda davidiana* J. Verreaux, 1870, "Mountains of Chinese Tibet" = plains of the Ourato (Suiyuan), Inner Mongolia.
Genus often subsumed into *Montifringilla*. Two subspecies recognized.
Distribution and Subspecies.
P. d. potanini Sushkin, 1925 – Russian Altai E to SE Transbaikalia and E Mongolia.
P. d. davidiana J. Verreaux, 1870 – S Mongolia and N China (S & E Inner Mongolia S to NE Qinghai).



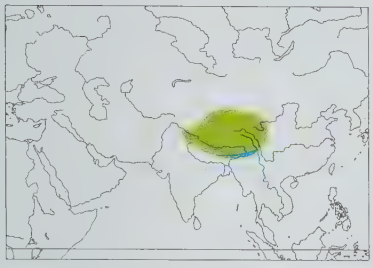
Descriptive notes. 12–15 cm; 20–25 g. One of the smaller ground-sparrows; relatively short wing and tail noticeable in flight. Nominate race has forehead, lores, chin and throat black, crown and upperparts tawny-brown, streaked darker on back, indistinct pale whitish-buff supercilium curving down behind pale fawn-brown ear-coverts; upperwing-coverts like back, greater coverts with pale buffy fringes, alula and primary coverts black, latter with pale bases, flight-feathers blackish with pale edging; central tail feathers blackish, outer feathers white or mostly grey; underparts white, breast often washed light buffish; iris brown; bill pale greyish to straw-coloured, tip black; legs dark grey to blackish. Sexes similar. Juvenile is paler than, lacks black on face. Race *potanini* is paler, more sandy-coloured and less streaked above than nominate. Voice. Rather silent; flocks give constant quiet twittering call as contact.
Habitat. Semi-desert, stony plains and rocky plateaux with short dry grass, desert edge, usually close to water on edges of marshes; 1000–3000 m, occasionally higher, to 4500 m.
Food and Feeding. Poorly studied. Small seeds of grasses and dwarf alpine plants, and insects. Spends most of the time on ground, where it moves rapidly; searches the dung of domestic animals for food items. In pairs and small groups; larger flocks outside breeding season.
Breeding. Season May–Jul/early Aug. Breeds as solitary pair or in loose colony. Strongly territorial. Nest constructed from dry grass, wool and soft plant material, placed 0·5–1 m from entrance in burrow of small mammal, including suslik (*Citellus*), pika (*Ochotona*) and hamster (*Cricetus*), material almost filling the cavity; can also excavate own cavity. Clutch 5–6 eggs; incubated by female. No other information.
Movements. Mainly sedentary; some post-breeding descent to lower altitudes, even to N of breeding range. Vagrants recorded in SE Turkmenistan and N India (Sikkim).
Status and Conservation. Not globally threatened. Sparsely distributed, but locally common to abundant.
Bibliography. Ali & Ripley (1974), Busching (2003), Cheng Tsohsin (1987), Clement *et al.* (1993), Dickinson (2003), Étchécopar & Hüe (1983), Flint *et al.* (1984), Fu Tongsheng *et al.* (1998), Gebauer & Kaiser (1994), Gebauer *et al.* (2006), Ivanitskii (1997), Neufeldt & Vietinghoff-Scheel (1978b), Piechocki & Bolod (1972), Qu Yanhua, Ericson *et al.* (2006), Qu Yanhua, Lei Fumin *et al.* (2002), Stepanyan (2003), Vaurie (1959).

38. Rufous-necked Ground-sparrow

Pyrgilauda ruficollis

French: Niverolle à cou roux **German**: Rothals-Erdsperling **Spanish**: Gorrión Cuellirrufo
Other common names: Rufous-necked Snowfinch, Red-necked Ground-sparrow/Snowfinch

Taxonomy. *Montifringilla ruficollis* Blanford, 1871, Kangra Lama Pass, north Sikkim, India.
Genus often subsumed into *Montifringilla*. Two subspecies recognized.
Subspecies and Distribution.
P. r. isabellina Stegmann, 1932 – N Tibetan Plateau from E Kunlun Shan and Altun Shan E to W Qilian Mts.
P. r. ruficollis (Blanford, 1871) – S & E Tibetan Plateau E to C China (SW Qinghai and W Sichuan), S to N Himalayas (N Nepal E to Sikkim).



Descriptive notes. 13–15 cm; 23–28 g. Distinctive ground-sparrow with small, pointed bill. Nominate race is mainly rufous-brown, with distinctive head pattern of grey crown, white supercilium, black line through eye and black moustachial streak, white cheek bordered at rear by reddish band that extends to side of neck; upperparts streaked darker brown, lower back to uppertail-coverts plain brown; upperwing brown, median and greater coverts with broad white tips, flight-feathers blackish with paler edging, white patch at base of secondaries and inner primaries; tail dark brown on central feather pair, outer feathers mostly white with dark tips; chin and throat white, underparts creamy white, side of breast with gingery wash; iris reddish-brown; bill dark grey, becoming black in breeding season; legs black. Sexes similar, female sometimes browner on head and with less white in wing. Juvenile is plainer and browner than adult. Race *isabellina* is paler than nominate. Voice. Call a soft "duuid" or "doooid"; calls used in song in display-flight accompanied by buzzing noises. Chattering alarm, likened to call of Common Magpie (*Pica pica*).
Habitat. High barren stony steppes and grassy plateaux, particularly on edges of small watercourses, rubbish tips near human habitations; associated with pika (*Ochotona*) and vole (*Microtus*) colonies, though less so than congeners. At 3500–5000 m.
Food and Feeding. Seeds and insects. Forages on ground, and searches dung of domestic animals. Runs extensively; can dig with legs and bill. In pairs and small flocks; larger flocks outside breeding season.
Breeding. Season May–Jun. Breeding in solitary pairs or small groups. Strongly territorial; in display-flight rises silently, sings in diving descent. Nest constructed with plant material, lined with hair, placed in rock hole or in burrow of small mammal, particularly Brandt's vole (*Microtus brandti*). Clutch 4–5 eggs. No other information.
Movements. Nomadic; moves to lower altitudes in winter.
Status and Conservation. Not globally threatened. Common in most of range; scarce at S limits in Nepal and N India.
Bibliography. Ali & Ripley (1974), Cheng Tsohsin (1987), Clement *et al.* (1993), Dickinson (2003), Étchécopar & Hüe (1983), Fu Tongsheng *et al.* (1998), Gebauer & Kaiser (1994), Gebauer *et al.* (2006), Lei Fumin *et al.* (2005), Moreau & Greenway (1962), Qu Yanhua, Ericson *et al.* (2006), Qu Yanhua, Lei Fumin *et al.* (2002), Rasmussen & Anderton (2005b), Schäfer (1938), Stegmann (1932), Vaurie (1959, 1972), Vietinghoff-Scheel (1980b).

39. Blanford's Ground-sparrow

Pyrgilauda blanfordi

French: Niverolle de Blanford **German**: Blanforderdsperling **Spanish**: Gorrión de Blanford
Other common names: Blanford's Finch/Snowfinch, Plain-backed Ground-sparrow/Snowfinch

Taxonomy. *Montifringilla Blanfordi* Hume, 1876, borders of Tibet to the north of Sikkim, Xizang, China.
Genus often subsumed into *Montifringilla*. Sometimes treated as conspecific with *P. theresae*, but significant plumage differences. Three subspecies recognized.
Subspecies and Distribution.
P. b. ventorum Stegmann, 1932 – NW China from SE Xinjiang (Altun Shan) E to NW Qinghai.
P. b. barbata Przevalski, 1887 – NC China (E Qinghai).
P. b. blanfordi (Hume, 1876) – Tibetan Plateau from S Qinghai S to E Ladakh, N Nepal and Sikkim.
Descriptive notes. 15 cm. Colourful finch-like bird with fairly small, conical bill, resembling *P. ruficollis*. Nominate race has characteristic face pattern of white forehead bisected by black, black line through eye and creamy-white cheek, reddish-chestnut nape, upper back and side of throat, and small black bib; upperparts sandy brown, streaked darker brown; upperwing-coverts like back, greater coverts with paler edges and tips, alula and primary coverts darker, flight-feathers dark brown with whitish edging, pale patch at base of secondaries and inner primaries (prominent in flight); central rectrices brown to grey-brown, remainder white with darker smudges and black (or black and white) tips; underparts creamy white, breast washed warm buffish; iris brown; bill slaty black; legs black. Sexes similar, female sometimes with head markings greyer, less black, than male's. Juvenile has head patter like washed-out version of adult, chin dark grey, throat and under-

parts greyish-buff, bill yellowish. Race *barbata* is greyer, less rufous, above than nominate; *ventorum* is generally much paler. Voice. Rapid twittering song, given both from ground and in display-flight.

Habitat. Dry sandy plains and stony areas on edges of sparse, grassy steppes and in neighbourhood of habitations; associates with pikas (*Ochotona*) and voles (*Microtus*). At 4000–5500 m.

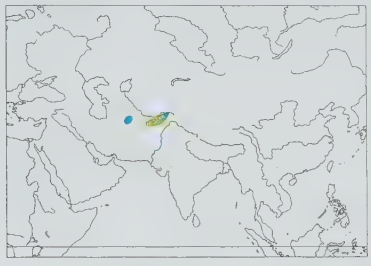
Food and Feeding. Seeds and insects. Forages on ground; runs extensively, digs with legs and bill. Forages near houses in winter. In pairs and small flocks; larger gatherings outside breeding.

Breeding. Few data. Nests recorded May to early Jun. Breeds in loose colony. Strongly territorial; has hovering display-flight. Nest in burrow of small mammal, principally pika or Brandt's vole (*Microtus brandti*). No other information.

Movements. Mainly sedentary; some movement to lower altitudes and S to N India in winter.

Status and Conservation. Not globally threatened. Common to locally common.

Bibliography. Ali & Ripley (1974), Cheng Tsohsin (1987), Clement *et al.* (1993), Dickinson (2003), Étchécopar & Hüe (1983), Fu Tongsheng *et al.* (1998), Gebauer & Kaiser (1994), Gebauer *et al.* (2006), Qu Yanhua, Ericson *et al.* (2006), Qu Yanhua, Lei Fumin *et al.* (2002), Rasmussen & Anderton (2005b), Roberts (1992), Schäfer (1938), Stegmann (1932), Vaurie (1959, 1972), Vietinghoff-Scheel (1981).



40. Afghan Ground-sparrow

Pyrgilauda theresae

French: Niverolle d'Afghanistan **German**: Afghanenerdsperling **Spanish**: Gorrión Afgano **Other common names**: Afghan Snowfinch, Theresa's Ground-sparrow/Snowfinch, Meinertzhagen's Snowfinch

Taxonomy. *Montifringilla theresae* R. Meinertzhagen, 1937, Shibar Pass, northern Afghanistan. Genus often subsumed into *Montifringilla*. Sometimes treated as conspecific with *P. blanfordi*, but significant plumage differences. Monotypic.

Distribution. N Afghanistan (N Hindu Kush Mts) and extreme S Tajikistan; some migrate to S Turkmenistan.

Descriptive notes. 13·5–15 cm; 18–35 g. Dull ground-sparrow with long, pointed bill. Male is mainly greyish-brown, with darker streaking on mantle; black from lores and narrowly around eye to chin and upper throat; median upperwing-coverts tipped whitish, greaters less prominently so, flight-feathers blackish with paler edging, bases of secondaries and of inner primaries white (conspicuous in flight); central tail feathers blackish, remainder white with blackish tips; underparts light buffish or buff-brown; iris reddish-brown; bill greyish-horn to black; legs black. Differs from superficially similar *Montifringilla nivalis* mainly in smaller size and slighter build, and fewer contrasts in plumage, with much less white in wing. Female is similar to male but duller, with less white in wing, and less marked black on lores and chin. Juvenile is more buffish than adult, has whitish chin and throat, yellowish bill. Voice. Little information. Calls include fast "zig zig", a sharp "tsi" alarm, and in flight a soft "kwaik".

Habitat. Open stony ground, slopes in mountains, flat steppes, in winter also farmland; 2400–3000 m.

Food and Feeding. Small seeds and insects; insects include weevils (Curculionidae) and ants (Formicidae). Forages on ground; runs extensively, digs with feet and bill. In small groups; large flocks outside breeding season.

Breeding. Season Jun. In loose colonies. Nest constructed mainly from animal fur and feathers, placed in hole of small rodent, mainly suslik (*Citellus*), 1 m or more from entrance, sometimes in tunnel among rocks. Clutch 5 eggs; young fed by both adults. No other information.

Movements. Resident; some descend in winter to lower altitudes, both to S and to N, reaching SE Turkmenistan.

Status and Conservation. Not globally threatened. Restricted-range species: present in Afghanistan Mountains Secondary Area. Common, but local.

Bibliography. Aichhorn (1970), Clement *et al.* (1993), Dementiev (1963), Dementiev *et al.* (1954, 1970), Dickinson (2003), Hüe & Étchécopar (1970), Rasmussen & Anderton (2005b), Tolstoj & Geipel (1990), Vaurie (1959), Vietinghoff-Scheel (1980a), Wood *et al.* (1978).
